Moving forward, it may be useful for clinicians and researchers to more precisely define "suppressive antibiotic therapy." The authors would suggest that SAT refer to "the chronic use of low-dose antibiotic therapy in patients with persistent PJI in which the aim is no longer to cure, but to prevent acute exacerbation or recurrence of local symptoms and/or greater systemic involvement." The key to this definition is the recognition that antibiotic therapy is not curative anymore in its intent. Suppressive antibiotic therapy is thereby differentiated from longer-than-standard "prolonged" administration of antibiotics meant to eradicate infection and cease after the infection is deemed to be cleared. Differentiation of these terms may allow future investigators to make more concrete recommendations regarding the use of SAT in shoulder PJI.

QUESTION 7: What are the recommendations for the route (intravenous (IV) vs. oral (PO)) and duration of postoperative antibiotic treatment when a one-stage revision arthroplasty is performed for subacute or chronic shoulder periprosthetic joint infection (PJI) of the shoulder caused by an indolent organism (e.g., *C. acnes* or coagulase-negative Staphylococcus)?

RECOMMENDATION: Prior to identification of pathogenic organisms from intraoperative cultures, a course of oral antibiotics may be initiated that covers the potential organism until intraoperative cultures are finalized. If the cultures are positive and periprosthetic infection is diagnosed, then a continued course of antibiotics (up to six weeks) should be pursued. There is no evidence to support a preferred route (PO vs. IV), type and duration of antibiotic treatment.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Periprosthetic shoulder infection negatively impacts the outcome of shoulder arthroplasty and is often treated with revision surgery [1]. The overall rate of infection after shoulder replacement is reported as 1.2-3.0% (0.5-3.9% for anatomic and up to 10.0% for reverse shoulder arthroplasty) [2–4]. Prosthetic shoulder infection commonly presents as painful arthroplasty and often lacks typical clinical findings of acute infection. Laboratory workup, such as inflammatory markers, white blood cell count and shoulder aspiration are usually negative, leaving clinicians with limited tools to confirm infection prior to revision surgery. This is mostly due to predominance of indolent organisms, such as *Cutibacterium acnes* (formerly known as *Propionibacterium acnes)* (39-66%) and *Coagulase negative staphylococcus* (24-28%) in periprosthetic shoulder infection [5,6]. Two-stage revision including aggressive debridement, antibiotic spacer placement followed by prolonged IV antibiotics was adopted by shoulder surgeons from treatment of PJI of other joints and showed 63-100% success rate in eradicating infection in short to mid-term follow up [7–9]. This approach has many short-comings, including subjecting patients to two operations and spacer complications, such as fracture, dislocation and loss of rotator cuff and bone stock, leading to poor joint function. Recently, one-stage revision has been advocated for low virulence indolent infections. Nelson et al. [10] and Cuff et al. [11] showed similar rates of eradication after one-stage versus two-stage revision arthroplasty. Beekman et al. reported results of single stage revision for infected reverse shoulder arthroplasty and showed at two year follow-up 90% of patients were infection free with a Constant score of 55.6% [4]. George et al. did a systematic review and found that the average Constant score was 51% after one-stage revision which was better than 41% two-stage revision [12]. These studies make a reasonable case for one-stage revision arthroplasty to eradicate indolent infections while preserving the function of the patient's joint, but they have highly variable protocols for type and duration of postoperative antibiotics. To answer the question above we review and summarize the limited evidence around antibiotic therapy following one-stage revision arthroplasty for periprosthetic shoulder infection with indolent organisms.

A PubMed search was conducted with terms arthroplasty, replacement, shoulder (Mesh) and revision which resulted in 120 papers. Abstracts of the papers were reviewed to identify papers reporting one-stage revision for indolent periprosthetic shoulder infection which resulted in 8 relevant articles that are included in this review.

Most authors retrospectively reporting their experience with treatment of shoulder arthroplasty infection incompletely report the antibiotic therapy following revision surgery. This section will review and summarize the current literature on treatment outcome of infected shoulder arthroplasty with specific focus on antibiotic regimen, as incomplete as it may be, including route (IV vs. PO), type and duration.

Grosso et al. [13] retrospectively reviewed patients with no perioperative sign of infection who underwent single stage revision shoulder arthroplasty and postoperatively had at least 1 positive culture and were not treated with an extended course of antibiotics. The majority of the cultures (56%) were *C. acnes* followed by coagulase negative staphylococci (CoNS) (35%). The rate of recurrence was very low (5.9%). Authors suggested unexpected cultures after a seemingly uninfected one-stage revision did not require extended antibiotic therapy.

Padegimas et al. [14] reviewed 117 one-stage revision shoulder arthroplasty with no preoperative concern for infection who were followed for more than 4 years and found that 28 (23.9%) had an unexpected positive culture postoperatively of which 15 (57.1%) were *C. acnes,* and majority were in male patients. They did not identify any predictor for reoperation, but they observed a higher rate of reoperation in patients without unexpected cultures (20.2% vs. 7.1%) but this did not reach clinical significance. In their cohort, 18 (64.3%) patients were treated with IV antibiotics for 6 weeks, and 10 (35.75) patients only received 2 weeks of PO antibiotics. There was only one reoperation among culture positive patients and that was in a patient who did not receive prolonged antibiotics.

Coste et al. [1] reported on the outcome of treatment in 42 patients with infected shoulder arthroplasty with a mean 34 months follow up. They defined infection based on seven criteria including

presence of a sinus tract, elevated serum white blood cell (WBC) count, elevated erythrocyte sedimentation rate, or C-reactive protein (CRP), positive culture including preoperative aspiration, X-ray evidence of implant loosening and positive bone scan, with no further details on how these criteria were weighted in their definition. There were 20 infections following primary arthroplasty and 22 after revision surgery. Thirty patients (71.4%) had subacute or chronic infection. At final follow up, 22 (73.3%) were infection-free, but there was a wide variation in how patients were treated. They were able to obtain antibiotic information in 30 patients and they judged treatment to be inadequate in 15 patients with regards to duration and type of antibiotics. Five patients were treated with antibiotics only, and only two remained infection-free at final follow up (60% failure rate).

Cuff et al. [11] reported their results of 22 patients with infection following hemiarthroplasty (n = 17) and open cuff repair (n = 5) treated with one versus two-stage revision. In their series, *S. aureus* was the most common organism. CoNS (n = 3) and *C. acnes* (n = 1) were also identified. None of their patients had recurrent infection at mean follow up of 43 months and there was no difference in any of the outcome measures between one versus two-stage revision. The majority of the patients were given six weeks of IV antibiotics, while patients with no clinical signs of infection and with negative intraoperative histology were treated with two weeks of IV antibiotics. It is not clear what type of IV antibiotics were perscribed.

Keller et al. [15] performed a retrospective study of orthopaedic hardware infection that was treated with debridement and retention of hardware, single-stage revision or without surgery to determine if treatment with six weeks of oral antibiotics alters the rate of success at one year. They only included patients who had two separate positive cultures of the same organism from samples taken with a sterile technique from the same site. Of the 89 patients in their study, 42 (47.2%) were infection-free at one year. Patients with methicillin-resistant *S. aureus* (MRSA) or gram-negative organisms, prior infection at the same site, and higher Charlson comorbidity score were less likely to achieve treatment success. They concluded that patients who were on oral suppression for 3-6 months had a significantly lower recurrence rate but continuing antibiotics beyond 6 months did not have the same benefit. Specifically, *C. acnes* infection (n = 32) was associated with a higher likelihood of treatment success at one year (odds ratio: 5.1, 95% confidence interval: 1.32-19.75).

Piggott et al. [16] reported a retrospective study of surgical and nonsurgical management of 24 patients with *C. acnes* PJI from one center with median follow up of 2 years. They defined definite PJI as two positive *C. acnes* cultures or one positive *C. acnes* culture plus sinus tract, clinical purulence or positive histopathology. Probable PJI was defined as one positive *C. acnes* infection and any suspicious clinical sign of infection. There were 11 (46%) definite and 13 (54%) probable PJI cases. The surgery group included 1 incision and debridement with retention, 4 one-stage revisions, 7 two-stage revisions and 3 spacer placements with no re-implantation. The median duration of antibiotic treatment was 6.3 months (range 1.3-50.7). They showed similar success rates with antibiotics only (67%) versus surgery plus antibiotic treatment (71%) (p = 1.0). Fifteen patients (71%) had rifampin as part of their antibiotic treatment but being on rifampin did not significantly change their outcome (73% vs. 60%; p = 0.61) and 40% of patients who received rifampin had to stop it due to side effects.

Hsu et al. [17] reported a retrospective study of 55 failed shoulder arthroplasty cases without clinical evidence of infection who underwent one-stage revision and compared their outcome at average 4 years between patients with ≥ 2 positive cultures (n = 27) and those with 1 or no positive cultures (n = 28). They reported comparable Simple Shoulder Test scores and reoperation rates. All patients received IV vancomycin and ceftriaxone as prophylaxis. If the index of suspicion for infection was high, the IV antibiotics were continued for 3 weeks until the cultures were finalized. If suspicion was low, the patients were started on oral amoxicillin and clavulanic acid for 3 weeks. If cultures were negative or only one culture was positive, antibiotic was stopped at 3 weeks. If ≥ 2 positive cultures became positive at any point, IV ceftriaxone +/- vancomycin was started and/or continued for 6 weeks. They reported 42% antibiotic side effects in this cohort which was higher than the IV antibiotics group.

Klatte et al. [18] retrospectively reviewed their experience with 26 infected shoulder arthroplasty patients treated with one-stage revision at mean follow-up of 4.7 years (range 1.1-13.3 years). The most common organisms were *Staphylococcus epidermis* and *C. acnes*. The majority of patients (94%) were infection-free at final follow up. Antibiotic therapy was tailored to clinical signs, serial CRP levels and serum WBC count. IV antibiotics were given for a mean of 10.6 days (range: 5-29 days). PO antibiotics were given to 4 patients for 5 days, 8 patients for 14 days and 2 patients for 24 days and stopped when CRP normalized and the wound had healed.

The literature on antibiotic treatment following one-stage revision shoulder arthroplasty for subacute and chronic infection is primarily based on heterogeneous case series with inconsistent definitions for infection, and variable treatment protocols. Shoulder PJI with indolent slow growing organisms, such as *C. acnes* and CNS, often have minimal clinical signs of infection. Thus, the diagnosis of infection is frequently made up to two weeks after the revision has been completed. As a practical approach to management, many clinicians recommend using antibiotics for all revision shoulder arthroplasty surgery pending the final cultures results [19].

There is no consensus on duration and type of antibiotics for this period. Antibiotic treatment after cultures are finalized should be dictated by the clinical index of suspicion for infection, culture results, and risk-benefit analysis of antibiotic side effects. There is no high-level evidence currently available to guide this decision.

Authors: Mandeep Virk, Mark Morrey

QUESTION 8: What are the recommendations regarding the route (intravenous (IV) vs. oral (PO)) and length of postoperative antibiotic treatment when a one-stage revision arthroplasty is performed for subacute/chronic shoulder periprosthetic joint infection (PJI) caused by a virulent organism (e.g., methicillin-sensitive *Staphylococcus aureus* (*S. aureus*), or MSSA, vs. methicillin-resistant *S. aureus* (MRSA), E. coli)?

RECOMMENDATION: Intravenous antibiotics or intravenous followed by oral antibiotics are both reasonable options for one-stage revision shoulder arthroplasty for subacute/chronic shoulder PJI caused by a virulent organism. As there is no consensus on the route or duration, these treatment parameters should be selected in consultation with an infectious disease specialist.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Single-stage revision shoulder arthroplasty is an option for infected shoulder arthroplasty [1–4]. However, the outcomes depending on the virulence of the organism and the ideal duration and mode of antibiotic (IV or oral) treatment associated with single stage revision for PJI is not known.

For this purpose, a comprehensive search on PubMed and Embase database of all English literature till March 2018 was conducted to query keywords: (shoulder OR 'upper extremity') AND (arthroplasty OR replacement) AND (infection OR infected). A total of 1,434 articles were retrieved by the initial search. After review of the title and abstract of all studies, articles focusing on "management of infection" were extracted for further review (n = 31). After applying final exclusion ("two stage revision," "antibiotic spacer" or "antibiotic suppression") and inclusion criteria ("single stage revision," "antibiotic"), a full text review of the articles was conducted, and 6 articles were selected for final analysis. Articles reporting single stage revision but without any information on antibiotic type and or duration were further excluded (n = 2).

The selected studies for analysis (n = 4) evaluated the role of postoperative antibiotic therapy for single stage revision shoulder arthroplasty for PJI. However, it must be emphasized that these studies did not stratify results by the virulence of the organism. Thus, no firm conclusions regarding treatment according to the virulence of the organism can be made.

Beekman et al. retrospectively reviewed 11 consecutive patients with an infected reverse shoulder arthroplasty who underwent single stage revision arthroplasty [5]. Two of these patients had monobacterial infection with a virulent organism (*Staphylococcus aureus* and *Escherichia coli*). Both of these patients received at least three days of IV antibiotic and were discharged on oral antibiotics, which were continued for at least three months. Ince et al. retrospectively reviewed 16 patients with an infected shoulder arthroplasty (three with identified virulent organisms) that underwent single stage revision shoulder arthroplasty [6]. Three patients (~19%) had undergone revision surgery prior to review. All patients received intravenous antibiotics for mean of 8.6 days (range: 5-14 days) and antibiotics were stopped when the surgical incision had healed and/or infection labs (erythrocyte sedimentation rate (ESR), C-reactive protein (CRP) and white blood cell (WBC) count) were down trending. No recurrence of infection was reported in 9 patients that were reviewed. Klatte et al. reported their results of single stage revision shoulder arthroplasty for PJI in 35 patients, of which 26 were available for review [7]. Patients received IV antibiotics for a mean of 10.6 days (range: 5-29 days), and 11 patients received PO antibiotics for a mean duration of 12.8 days (range: 5-24 days). There were two recurrences. Cuff et al. retrospectively reviewed 22 infected shoulder arthroplasties of which 11 were treated with single stage revision to reverse shoulder arthroplasty and intravenous antibiotics [8]. Five of the 10 patients had virulent pathogens. Patients received antibiotics for 2 (1 patient) or 6 (4 patients) weeks depending on cultures and intraoperative histology results. There was one recurrence of infection.

There is little evidence regarding the subsequent antibiotic management of subacute and chronic shoulder PJI due to high viru-

lence organisms treated with one-stage revision. IV antibiotics or IV followed by PO antibiotics are both reasonable options. However, there is no consensus on the antibiotic type and duration of antibiotic treatment. Presently, clinical judgement and normalization of infection labs (ESR and CRP) for six weeks, if elevated preoperatively, are helpful in determining the duration of antibiotic treatment.

Authors: Ben Clark, Jim Kelly, John Itamura, Natividad Benito

QUESTION 9: What is the optimal antibiotic treatment for culture-negative cases with positive clinical, radiographic or intraoperative findings for acute shoulder periprosthetic joint infection (PJI)?

RECOMMENDATION: The limited data suggests treatment should consist of an empiric antibiotic regimen recommended by an infectious disease specialist considering the local organism profile.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

The incidence of culture-negative PJI ranges from 5 to 34% [1]. The following predefined keywords were used during the search using Medline database: ("culture negative") AND ((prosthetic joint infection OR periprosthetic joint infection) OR (arthroplasty AND infection)). Nine original articles [2–11] and a single systematic review [12] have been published on the topic of culture-negative PJI. However, these studies have addressed culture-negative PJI of knee and hip arthroplasty, but not prosthetic shoulder or elbow infections, and have focused on outcomes of culture-negative versus culture-positive PJI (not on the best treatment). The existing publications indicate that the outcome of a patient with culture-negative PJI is similar to that of PJI with a pathogen identified. In these studies, most of these patients with culture-negative PJI have been treated with glycopeptides, mainly vancomycin. Previous antibiotic use was common in these patients, potentially confounding the ability to culture an organism [13].

In a large multicenter study of the microbial etiology of PJI that included more than 2500 PJI cases in Spain [14], Benito et al. analyzed the microbiology of 42 infections of shoulder arthroplasty (data not published); twenty-eight (66.7%) PJIs were caused by aerobic gram-positive cocci, mainly coagulase-negative Staphylococci, followed by *S. aureus*; nine (21.4%) were due to *Cutibacterium* spp. and another nine (21.4%) to *Enterobacteriaceae*; two cases were caused by *Pseudomonas* aeruginosa; five (11.9%) of the PJI cases were polymicrobial infections.

Given the limited nature of the available data, the antibiotic treatment recommended for culture-negative cases of acute shoulder PJI with positive clinical, radiographic or intraoperative findings remains unclear. It is recommended to work with an infectious disease consultant to arrive at a treatment strategy which includes, in addition to surgical irrigation and debridement with exchange of modular elements, empiric coverage against the most common pathogens of acute PJI. A broad-spectrum antibiotic regimen that covers aerobic gram-positive cocci (including methicillin-resistant *Staphylococcus aureus* and coagulase-negative staphylococci) and gram-negative bacilli, as well as *Cutibacterium* species, could be recommended. The need for antibiotic activity against specific multidrug-resistant microorganisms should be considered according to the patient's clinical and epidemiological background.

Treatment with vancomycin or teicoplanin or daptomycin would cover aerobic gram-positive cocci (mainly Staphylococci), in other words, 67% of infections according to the mentioned data. These antibiotics are also active against *Cutibacterium* spp.; however, a beta-lactam (penicillin or cephalosporins) would probably be more active than vancomycin according to a study of 28 strains of *C. acnes* isolated from shoulder surgery [15]. *C. acnes* is highly susceptible to a wide range of antibiotics, including beta-lactams, quinolones, clindamycin and rifampin [16]. However, resistance is beginning to emerge. Recent reports note an increasing emergence of resistance to macrolides, clindamycin, tetracycline and trimethoprim-sulfamethoxazole [16].

- Aerobic gram-negative bacilli would mainly include *Enterobacteriaceae* and *P. aeruginosa*. Besides of the coverture of aerobic gram-positive cocci (with vancomicin, teicoplanin or daptomicin), adding ceftriaxone would be a good option in order to additionally cover *Enterobacteriaceae*, (if there are no suspicion of mechanisms of *Enterobacteriaceae* acquired

resistance such as extended-spectrum beta-lactamases producing (ESBL) *Enterobacteriaceae*). Ceftriaxone is also very active against *Cutibacterium* spp. If *P. aeruginosa* is a concern, cefepime or ceftazidime (instead of ceftriaxone) should be considered. Meropenem (instead of a cephalosporin) would be an option if ESBL-*Enterobacteriaceae* are suspected; it also has activity against *P. aeruginosa*.

- Clearly knowing the organism and antibiotic susceptibility allows for the selection of an antibiotic which is maximally bactericidal to the specific pathogen and minimally toxic to the patient. However, in lieu of this data, the empirical treatment should be typically administered intravenously; the possibility of a second phase with oral antimicrobial treatment should be evaluated on a case by case basis. Consideration of antimicrobial coverage provided before the culture was taken could help to choose the antibiotic regimen, as the clinician may presume the preoperative antibiotic is effective and, theoretically, is the reason the bacteria did not grow in culture. The role of rifampin is not clear in the scenario of a culture-negative PJI, as it has demonstrated its efficacy only in the staphylococcal infections. Moreover, the emergence of resistance with rifampin is high if it is used without another simultaneous antibiotic to which the pathogen is susceptible, and this cannot be guaranteed in a culture-negative PJI.

Long courses of antimicrobial treatment are recommended for infections of hip (3 months) and knee (6 months) prostheses managed with debridement, antibiotics and implant retention (DAIR) [17]. Based on many observational studies and one clinical trial [18] most patients with acute PJI managed with DAIR may be safely treated for 8 weeks [13]. Available information on this topic refers to prosthetic knee and hip infections, and it remains unclear how this data applies to shoulder PJI, where the microbiology of infection varies compared with hip and knee.

QUESTION 10: What is the optimal antibiotic treatment for culture-negative cases with positive clinical, radiographic or intraoperative findings for subacute or chronic shoulder periprosthetic joint infection (PJI)?

RECOMMENDATION: The limited data suggests treatment should consist of an empiric antibiotic regimen recommended by an infectious disease specialist considering the local organism profile.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

A systematic review was conducted in March 2018 using PubMed and Google Scholar databases. Keywords included "shoulder" AND ("prosthetic joint infection" OR "arthroplasty infection") AND ("culture" or "culture-negative"). After title and abstract review, fourteen studies were considered for inclusion; additional references were identified from review of reference lists.

There are no studies that have reported clinical outcomes for culture-negative shoulder arthroplasty infections stratified by antimicrobials utilized. There are limited observational data on empiric antimicrobial treatment options for patients with non-shoulder arthroplasty infections. Antimicrobials for culture-negative infections should be selected in light of suspected organisms and their typical antimicrobial resistance profiles, drug tissue penetration (including bone penetration), bioavailability (if oral antimicrobials are selected), host factors (including comorbidities and allergies) and safety considerations. Prior antimicrobial exposure may inform organisms suppressed from culture growth. Additional considerations include the type of surgical procedure, such as whether hardware is retained or exchanged and the use of antimicrobial-laden cement. In the shoulder, most culture-positive subacute and chronic infections are due to coagulase-negative Staphylococci and *Cutibacterium* species [1–3]. Limited evidence in non-shoulder arthroplasty settings have reported good outcomes with vancomycin [4,5] and cephalosporins [5,6]. Most studies in the non-shoulder literature did not find culture negativity to be a poor prognostic factor [5–11], although one study [12] did find worse outcomes in culture-negative knees treated with irrigation and debridement.

The addition of rifampin may be considered if there is strong suspicion for gram-positive infection, particularly staphylococcal, in the setting of maintained hardware [13]. Synergy in the laboratory has been shown with rifampin for *Cutibacterium* [14]; however, there is insufficient clinical experience on the role of rifampin for the treatment of *Cutibacterium* infection to endorse its use [15]. Rifampin should never be used in monotherapy as resistance rapidly emerges; when employed rifampin should be used with careful monitoring and with full consideration of drug toxicities and drug interactions.

Prior antimicrobial exposure is a strong risk factor for culture-negativity [5,7,16]. When infection is suspected, antibiotics should be withheld prior to surgery whenever possible to reduce the likelihood of culture-negative infection. Whether a single dose of perioperative antimicrobial prophylaxis reduces the yield of organisms in low-burden infection is uncertain; two small randomized studies on hip and knee PJI suggest that a single dose of perioperative antibiotic therapy does not reduce operative culture yield [17,18]. Multiple operative samples should also be collected to increase the overall culture yield and to guard against placing too much emphasis on a single positive culture that, in some cases, may be a contaminant [19,20]. Aseptic inflammation and unusual organisms should also be considered in the differential of the culture-negative infection. In these cases, with concern for infection, pathology may be helpful to identify granulomas or other signs of atypical infection; thus, sending tissue samples for pathology is recommended to assist in properly interpreting any culture results. In the appropriate clinical and epidemiologic context, for example in immunocompromised hosts, and, in the setting of penetrating trauma, fungal and mycobacterial cultures should also be considered.

3.3. TREATMENT: BONE GRAFT

Author: Michael Khazzam

QUESTION 1: Should bone graft or cement be removed during treatment of acute shoulder periprosthetic joint infection (PJI)?

RECOMMENDATION: Unknown. There are no reported investigations to guide the decision-making process regarding how to manage cement and/or autograft bone graft in the setting of shoulder PJI.

LEVEL OF EVIDENCE: No Evidence

DELEGATE VOTE: Agree: 90%, Disagree: 5%, Abstain: 5% (Super Majority, Strong Consensus)

RATIONALE

There is no current literature to guide evidence-based recommendations regarding how to manage autograft bone or cement in the setting of acute infection after primary shoulder arthroplasty. Additionally, it is unknown how or if complete removal of this material is necessary to eradicate shoulder PJI. The goal of surgical intervention in the setting of PJI is to debride any material that may result in persistent infection including surfaces with biofilm. Complete removal of autograft bone or cement at times can be extremely difficult and can result in significant bone loss especially if bone graft was used to reconstruct glenoid bone deficiency. A long stem, cemented, well-fixed humeral stem requires a humeral osteotomy or cortical window for complete cement removal which adds significant additional morbidity to the revision procedure. The significance of retaining these materials is unclear and, in order to avoid the complications that come with complete removal of these materials, investigation is needed to understand the risks associated with incomplete removal of cement or bone graft and the risks of recurrent PJI that are associated with this practice. Additionally, it is unknown whether retention of this material requires a change in the postoperative antibiotic management. Finally, it is also unknown how the species of bacterial pathogen and antibiotic sensitivity profile may influence the successful treatment of PJI. Future investigation is required to answer this question in an evidence-based fashion.

Methods

Systematic review of the literature was performed using MeSH terms: cement and infection and shoulder arthroplasty/ replacement, cement and retention and infection, bone graft and infection and shoulder arthroplasty/replacement using search engines PubMed, Web of Science, and CINAHL. Inclusion criteria for this systematic review were Level of Evidence I-IV, English language, shoulder arthroplasty studies which included patient who underwent treatment for PJI and evaluation of the impact of cement removal and/or autograft bone removal classified as either acute, subacute, or chronic infection. Exclusion criteria were non-English language articles, review papers, technique papers, non-human studies, biomechanics or basic science papers, and articles that discussed only hip and or knee arthroplasty PJI. The Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) criteria were used manage the data of this review. The initial search produced 213 abstracts; all of these were excluded as they did not contain any details or evaluation of the question under investigation. Therefore, there are no current studies to reference the impact or effects of cement removal or autograft bone removal in the setting of shoulder arthroplasty PJI for acute, subacute or chronic infection.

Author: Michael Khazzam

QUESTION 2: Should bone graft or cement be removed in treatment for subacute or chronic shoulder periprosthetic joint infection (PJI)?

RECOMMENDATION: Unknown. There are no reported investigations to guide the decision-making process regarding how to manage cement and/or autograft bone graft in the setting of shoulder PJI. An attempt should be made to remove all loose, necrotic and foreign material.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

A systematic review of the literature was performed using "MeSH terms:" cement and infection and shoulder arthroplasty/ replacement, cement and retention and infection, bone graft and infection and shoulder arthroplasty/replacement using search engines PubMed, Web of Science, and CINAHL. Inclusion criteria for this systematic review were Level of Evidence I-IV, English Language, shoulder arthroplasty studies which included patient who underwent treatment for PJI and evaluated the impact of cement removal and or autograft bone removal classified as either acute, subacute, or chronic infection. Exclusion criteria were non-English language arti-

cles, review papers, technique papers, non-human studies, biomechanics or basic science papers, articles that discussed only hip and or knee arthroplasty PJI. The Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) criteria were used manage the data of this review. The initial search produced 213 abstracts, all of these were excluded as they did not contain any details or evaluation of the question under investigation. Therefore, there are no current studies to reference the impact or effects of cement removal or autograft bone removal in the setting of shoulder arthroplasty PJI for acute, subacute or chronic infection.

There is no current literature to guide an evidence-based recommendation regarding how to manage autograft bone or cement that was placed at the time of primary shoulder arthroplasty and has become infected. Additionally, what is unknown is how or if complete removal of this material is necessary to eradicate shoulder PJI. The goal of surgical intervention in the setting of PJI to debride any material that may result in retained biofilm that, if not removed, may result in a recurrent infection. Complete removal of autograft bone or cement at times can be extremely difficult and can result in significant bone loss especially if bone graft was used to reconstruct bone deficiency of the glenoid. A long stem cemented well-fixed humeral stem can at times require a long humeral osteotomy or cortical windows for complete cement removal which adds significant additional morbidity to the revision procedure.

The significance of retaining these materials is unclear and investigation is needed to understand the risks associated with incomplete removal of cement or bone graft, and what risks of recurrent PJI are associated with this practice to avoid the morbidity that may come with complete removal of these materials. Additionally, it is unknown how retention of this material requires a change in the postoperative antibiotic recommendations for the type, method of delivery or duration of treatment. Finally, it is also unknown how the species of the bacterial pathogen may influence the successful treatment and risk of recurrent PJI, where some less virulent pathogens (such as *C. acnes*) may be more difficult to eradicate with retention of cement or bone graft because of the slow growing nature. Future investigation related to the impact of type of bacteria can provide data to develop a treatment algorithm for which cases can predictably be successful with retention of cement or graft and for which settings require complete removal of all graft and cement materials.

3.4. TREATMENT: COMPONENT RETENTION

Author: Michael Khazzam

QUESTION 1: Is there a role for irrigation and debridement (I&D) with implant retention when treating acute shoulder periprosthetic joint infection (PJI)?

RECOMMENDATION: There is insufficient high-quality evidence to support or discourage the use of I&D with implant retention to treat acute shoulder PJI.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 96%, Disagree: 4%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

There is little data demonstrating the outcome or infection-free implant survivorship for the treatment of acute shoulder PJI with I&D and implant retention. To date, there are only 37 patients (38 shoulders) with outcomes following this procedure reported in the literature [1–4]. These studies were all grade IV level of evidence (LOE) retrospective case series and demonstrated a 50% failure rate (defined as continued infection) and requiring additional treatment. Three of four studies treated acute, subacute and chronic infections using this technique, but the sample size was too small to analyze how time of infection influences outcomes [1,3,4]. For example, Jacquot et al. found that 1 of the 2 shoulders classified as chronic PJI, 2 of 4 subacute, and 2 of 7 acute had recurrent infection requiring additional treatment [3].

Dennison et al. was the only study found specifically investigating the efficiency of acute (surgery within 6 weeks following index arthroplasty and less than 3 weeks of symptoms) and "delayed onset/delayed acute" (more than 6 weeks following index arthroplasty with symptoms less than 3 weeks) [2]. This retrospective LOE IV case series examined 9 patients (10 shoulders) and found 3 of 10 had recurrent infection requiring resection arthroplasty (mean follow up 4.1 years range 0.58-12.8 years). The method of I&D varied in this study with 3 performed arthroscopically and 7 open. All of the subjects requiring resection had their I&D performed open; the numbers were too small to perform any meaningful analysis of how this may influence outcomes or infection free survivorship. Additionally, 6 of 10 shoulders were maintained on chronic suppressive antibiotics indefinitely without explanation of why the authors selected this treatment.

Further research will be needed to determine how irrigation and debridement with implant retention plays a role in the treatment algorithm of PJI. Specific attention towards answering the questions regarding the effect of the pathogen and the antibiotic sensitivity profile; surgical approach (open or arthroscopic); timing from presentation and index arthroplasty; need for exchange of modular component parts; and type, duration, and method of delivery of antibiotics will be critical to guide these treatment decisions.

Methods

A systematic review was performed using MeSH terms: "I&D shoulder arthroplasty/shoulder replacement, single staged shoulder arthroplasty/shoulder replacement, implant retention revision shoulder arthroplasty/shoulder replacement, acute infection shoulder arthroplasty/ shoulder replacement" using search engines PubMed, Web of Science, and CINAHL. The inclusion criteria for

this systematic review were LOE I-IV, English language, shoulder arthroplasty studies that included patients who underwent treatment for PJI using I&D with component retention (polyethylene and or glenosphere exchange without stem or baseplate removal was included). Exclusion criteria were non-English language articles, review papers, technique papers, non-human studies, and studies that only presented data on one-stage or two-stage revision, hip or knee arthroplasty articles. The Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) criteria were used manage the data of this review. Our initial search produced 66 abstracts; 61 were excluded, because they did not fulfill the inclusion criteria, and the remaining 4 manuscripts were obtained and reviewed to assure inclusion criteria. Additionally, the references of these manuscripts were reviewed to ensure no additional material would be missed. This left four studies for analysis, only one of which evaluated the role for I&D with implant retention for the treatment of acute shoulder PJI.

Authors: Jeremy Somerson, William Levine

QUESTION 2: What are the indications for irrigation and debridement (I&D) with component retention in subacute or chronic shoulder periprosthetic joint infection (PJI)?

RECOMMENDATION: I&D with component retention alone for subacute/chronic shoulder PJI in the literature is less successful than component explant, but may play a role in select patients.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 96%, Disagree: 0%, Abstain: 4% (Unanimous, Strongest Consensus)

RATIONALE

A systematic review was performed using PubMed and Google Scholar databases in February 2018 to identify studies regarding the treatment outcomes after shoulder arthroplasty. The keywords included "shoulder AND (replacement OR arthroplasty) AND infection." This identified 46 articles with relevance to surgical treatment of shoulder PJI; 10 of which described treatment with debridement and implant retention for subacute/chronic infection.

I&D with component retention for shoulder PJI in the subacute and chronic setting has shown low rates of eradication of infection [1–10]. Of the 51 surgical cases identified in studies with a reported eradication rate, approximately half (n = 24, 47%) were successfully cured with debridement alone. The majority of these successful treatments were from two recent studies that integrated modular component exchange with partial component retention [1,2].

Stone et al. [1] reported on patients with shoulder PJI treated with one-stage partial component exchange compared to patients with one-stage complete hardware removal and two-stage revisions. The greatest success rate was with complete one-stage revisions (96% eradication of infection) compared to only 63% eradication for partial one-stage revisions. The authors concluded that there are some circumstances in which retaining a prosthesis may be preferred (such as well-fixed components), but that the surgeon must be aware of a higher risk of recurrent infection.

A French multicenter study reported on 32 patients who underwent revision for infection after reverse shoulder arthroplasty (RSA); of these, 13 patients underwent debridement, modular component exchange and partial component retention [2]. Only 7 patients (54%) were successfully cleared of infection with debridement alone. However, the 15% complication rate reported with debridement was lower than that reported for resection (33%), one-stage revision (20%) or two-stage revision (36%). The authors propose that initial debridement be considered for primary treatment of infected RSA given that more than half of patients were successfully treated with relatively few complications.

Primary treatment of subacute/chronic shoulder PJI with debridement, irrigation and component retention is an option, particularly in patients in which the risks of more aggressive surgery outweigh the potential benefits. However, patients and surgeons should be aware that the published rate of recurrence is substantially greater with this strategy compared to one- or two-stage revision.

QUESTION 3: Should modular components be exchanged during irrigation and debridement (I&D) of acute shoulder periprosthetic joint infection (PJI)?

RECOMMENDATION: Whilst there is logic in exchanging non-fixed modular components, such as the bearing surfaces, to allow thorough I&D of the entire effective joint space and removal of as much biofilm as possible, there is insufficient literature to provide clear guidance.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

A thorough search of the PubMed database for manuscripts addressing the exchange of modular parts during shoulder I&D for acute PJI was undertaken. Five papers were found that recorded if modular components were exchanged [1–5], totalling 53 patients. The pooled infection-free survivorship was 65% in the "modular exchange group" (19/29) versus 58% (14/24) in the "no exchange group" ($p = 0.77$ Fisher's exact test).

Of these papers, three [1,3,5] specified the outcome for patients with acute debridement and retention with and without modular exchange. In total, 10 patients underwent acute debridement and retention of prosthesis without modular exchange with an infection free survivorship of 70% (7/10). Eight patients are recorded as having undergone poly exchange during debridement of an acute infection, with an infection free survivorship of 62.5% (5/8; $p > 0.05$).

QUESTION 4: Should modular components be exchanged during irrigation and debridement (I&D) of subacute or chronic shoulder periprosthetic joint infection (PJI)?

RECOMMENDATION: We defer to the response for the Question 5: "Should well-fixed glenoid components be removed during surgical treatment for subacute or chronic shoulder PJI?"

It would seem that the recommendation, although of limited strength, would be for well-fixed components to be removed during surgical intervention for subacute/chronic shoulder PJI. Therefore, it can be extrapolated that modular components, which can be exchanged to remove biofilm with far less morbidity than well-fixed components, should likewise be either exchanged or removed and replaced with an antibiotic spacer.

LEVEL OF EVIDENCE: No Evidence

DELEGATE VOTE: Agree: 95%, Disagree: 5%, Abstain: 0% (Unanimous, Strongest Consensus)

Author: Surena Namdari

QUESTION 5: Should well-fixed glenoid components be removed during surgical treatment for subacute or chronic shoulder periprosthetic joint infection (PJI)?

RECOMMENDATION: Based on the higher rate of reinfection with component retention, we recommend removal of even well-fixed glenoid components in cases of single-stage revision for suspected subacute/chronic PJI. Certainly, there may be cases (i.e., high-risk surgical patients) where the patient and surgeon may choose to accept the higher failure rate with component retention in order to avoid surgical morbidity introduced by removing well-fixed components.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

A comprehensive literature review was performed to identify all studies on surgical treatment of subacute and chronic shoulder PJI. Previously, we have performed a systematic review on shoulder PJI treatment. In that study, we searched for the terms "shoulder arthroplasty infection" and "shoulder replacement infection" using the search engines PubMed and Embase through April 2014. Inclusion criteria were titles that specified periprosthetic infection of the shoulder (if "Periprosthetic infection" was mentioned, but no joint was specified, the article was included for further review) and articles pertaining to revision shoulder arthroplasty. Exclusion criteria were duplicate titles, review articles, editorials, technique articles without reported patient outcomes and instructional course lecture articles. Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) criteria were followed. For this question, the same search terms were used and the dates between May 2014 and February 2018 were searched in order to update the previous systematic review. The prior systematic review identified 663 titles, and an additional 243 were evaluated for the updated review.

In this updated systematic review, three additional studies were identified that met inclusion and exclusion criteria and added to the data from the prior systematic review by Nelson et al. [1] that involved a search until April 2014. Only the study by Jacquot et al. [2] defined a subset of patients treated for subacute or chronic PJI, and the other studies grouped both acute and chronic cases. Based on the available data (all retrospective), there is clearly a higher failure rate of treatment when components are retained (31.3%) as opposed to exchanged via a one-stage or two-stage procedure (< 10%) [1]. Because of this, one must recommend for treatment of subacute/chronic shoulder PJI with removal of all, even well-fixed, components. However, it should be noted that these studies were all based on retrospective review of patients treated according to surgeon preference, and the features of the particular infections are not well documented (bacteria, antibiotic sensitivity, etc.). It is possible, perhaps even probable, that patients treated with implant retention versus removal may have had different infectious presentations that led the treating surgeon to their chosen approach. Further comparative research is needed on this topic. In addition, there may be cases (i.e., high-risk surgical patients) where the patient and surgeon may choose to accept the higher failure rate with component retention in order to minimize surgical morbidity.

QUESTION 6: Is there a role for routine exchange of all well-fixed implants in revision shoulder arthroplasty without clinical or radiographic signs of infection?

RECOMMENDATION: Unknown. Even in the setting of possible subsequent unexpected positive cultures, there is sparse literature on the routine exchange of well-fixed implants in revision shoulder arthroplasty.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 96%, Disagree: 0%, Abstain: 4% (Unanimous, Strongest Consensus)

RATIONALE

Periprosthetic shoulder infection is one of the most challenging complications of shoulder arthroplasty [1,2]. The difficulty of diagnosis and treatment is attributed to *Cutibacterium acnes* which is a microorganism with low antigenicity [3]. Unlike knee and hip PJI, laboratory tests may be inadequate for diagnosing indolent infection caused by this agent [2]. The prevalence of *Cutibacterium acnes* has been reported to be as high as 50% of intraoperative cultures obtained at the time of revision surgery for a painful and stiff total shoulder arthroplasty [1]. This determination led to the definition of a new clinical entity: "Unexpected positive intraoperative cultures." Due to the fact that this bacterium is a member of the normal skin flora of the shoulder region, it is unknown whether a positive culture should be interpreted as a contamination or a definitive infection [4,5]. Due to the inadequacy of gram stain and frozen-section, and long incubation time; it is difficult to make a decision regarding implant removal during revision surgery [2]. Moreover, in the case of the well-fixed implants, the explant procedure can be difficult and have associated morbidity [5–7].

There is lack of evidence regarding the role for revision of well-fixed implants in revision shoulder arthroplasty without clinical or radiographic signs of infection [2,8]. In a study by Pottinger et al., [8] it has been reported that implants may need to be removed in patients who have risk factors for positive culture. McGoldrick et al. [9] have suggested single-stage reimplantation in the presence of loose implants. However, the authors have not commented on well-fixed implants. Similarly, Grosso et al. [6] have reported low recurrence with the removal of all components and single-stage reimplantation in the patients with unexpected positive intraoperative cultures. On the other hand, Topolski et al. [10] and Kelly et al. [11] reported high recurrence with the retention of implants. Lutz et al. [12] have evaluated infection with *Cutibacterium acnes* in the patients who underwent osteosynthesis or arthroplasty in the shoulder, knee or hip regions and reported that the absence of sepsis findings could not exclude the infection. The authors emphasized that the removal of the implants was important in the success of the treatment of *Cutibacterium acnes* infection of prosthetic material.

3.5. TREATMENT: IMPLANT

Authors: Mark Frankle, Jason Hsu

QUESTION 1: What is the optimal implant for treatment of acute periprosthetic joint infection (PJI): reverse total shoulder arthroplasty (TSA), anatomic total shoulder arthroplasty (aTSA) versus hemiarthroplasty?

RECOMMENDATION: The optimal implant for treatment of acute PJI is dependent on the status of the rotator cuff, humeral and glenoid bone stock, and patient factors.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 96%, Disagree: 0%, Abstain: 4% (Unanimous, Strongest Consensus)

RATIONALE

Acute shoulder PJI is most commonly considered to be an infection presenting within 3 months after index arthroplasty as described by Sperling et al. [1]. In this scenario, the surgeon has a number of options in the treatment of acute PJI including antibiotic treatment alone, debridement with or without exchange of modular components, single stage complete exchange, two-stage exchange with antibiotic spacer, indefinite implantation of an antibiotic spacer and resection arthroplasty.

Methodology

Using the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines, we conducted a systematic review to identify all studies concerning diagnosis and treatment of "infection" at the time of revision shoulder arthroplasty. We searched for all studies published in English using the terms (("revision" OR "failed") AND "shoulder" AND ("arthroplasty" OR "replacement")) limited to dates between January 1, 1996 and February 3, 2018. A total of 2,354 studies were identified. We reviewed the titles and abstracts of all studies and excluded studies that included patients with shoulder infection without arthroplasty or included patients with arthroplasty of joints other than the shoulder. The reference lists for all included studies were searched for any additional references and three references were added to our list. A total of 42 studies met inclusion criteria and were included in the final analysis. Relevant data were extracted from the selected publications, including stratification of acute/subacute/chronic classification, procedures performed, final implants, reinfection rates and functional/clinical results.

Results are summarized in Table 1. Of 42 studies, 19 stratified acute PJI from subacute/chronic PJI with 20% of included patients (93/459) in the acute category. While there were a fair number of studies that described patients with acute PJI, the types of implants explanted and implanted were not regularly reported or stratified; and, therefore, drawing conclusions regarding reinfection rates and clinical outcomes was limited. Also, a clear obstacle in synthesizing the literature was that no consensus definition for shoulder PJI was utilized by these studies [2], and defining reinfection is highly variable in the literature, making the optimal implant of choice for treatment difficult to determine. It should be noted that this review does not include data based on duration of symptoms which may play an important role in choice of intervention.

Indications for Irrigation and Debridement

Irrigation and debridement (I&D) with component retention or exchange of modular components is often considered a reasonable option in acute PJI. This has variable outcomes in the literature with regards to reinfection rates and clinical outcomes (Table 2) [1,3–12]. When aggregated, these 11 studies report a **42% recurrence rate for acute PJI treated with I&D** (19 of 45 patients). Given this data, the surgeon must weigh the risks of recurrent infection with and morbidity of implant removal. The decision on whether to perform an I&D may also depend on the acuity of symptoms with some studies suggesting low recurrence when performed within 2 weeks of symptom onset, even when the time between index surgery and symptom onset is prolonged [6,12] (i.e., secondary hematogenous infection [13]).

Indications for Reverse Shoulder Arthroplasty

Conversion to reverse shoulder arthroplasty may be preferred to an anatomic implant in cases of rotator cuff deficiency and proximal humeral and or glenoid bone loss [6,14,15]. In the setting of a prosthetic shoulder infection, a thorough debridement is required and often necessitates resection of necrotic and infected tissue for adequate infection control. Both infection and soft tissue loss are associated with poor functional outcomes after revision arthroplasty, and implantation of an anatomic implant may not be able to sufficiently compensate for rotator cuff loss and/or instability [15–17]. A reverse implant may better compensate for soft tissue loss or bony deficiency [15,18] and can improve pain control and functional recovery without a high recurrent infection rate in some studies [4,19–22].

In some reports, treatment with a reverse shoulder arthroplasty as a treatment for failed arthroplasty is associated with sub-optimal functional results and a high rate of complication [23–30]. Therefore, hemiarthroplasty should be a consideration in cases in which minimizing complications and further surgery is a priority [31,32].

Indications for Hemiarthroplasty

In cases of acute PJI in a shoulder with an intact rotator cuff, revision to hemiarthroplasty is also a reasonable option with potentially similar results to reverse arthroplasty in the setting of infection [19,33,34]. In addition, in some cases of substantial glenoid bone loss, recurrent instability of a reverse and patient factors, such as

noncompliance precluding implantation of a reverse, conversion to a hemiarthroplasty [32] may be the preferred choice to minimize intraoperative and postoperative complications [35].

Indications for Total Shoulder Arthroplasty

While better pain relief and functional scores can be obtained with total shoulder arthroplasty than hemiarthroplasty [36], the rate of polyethylene glenoid component loosening in the setting of revision is high [37]. In the setting of acute PJI, conversion to total shoulder should be strictly limited to cases in which the rotator cuff is fully intact, glenoid bone stock is sufficient, and bacterial burden is minimal.

In select cases, resection arthroplasty [38–42] and indefinite placement of an antibiotic spacer [43–45] can be considered for acute PJI.

3.6. TREATMENT: RESECTION

Authors: José M. Mora, Simon Lambert

QUESTION 1: What are the indications for resection shoulder arthroplasty in acute periprosthetic joint infection (PJI)?

RECOMMENDATION: There are no available reports on resection shoulder arthroplasty for acute PJI. At this time there is no evidence to routinely recommend this treatment for this indication.

LEVEL OF EVIDENCE: No Evidence

DELEGATE VOTE: Agree: 88%, Disagree: 8%, Abstain: 4% (Super Majority, Strong Consensus)

RATIONALE

Search Strategy

A request via the Royal Society of Medicine Library utilizing ProQuest Dialog, searching Embase and Medline archives. Search terms: (excision arthroplasty) OR (resection arthroplasty) AND (acute periprosthetic infection) OR (chronic periprosthetic infection) OR (subacute periprosthetic infection). Yielded 1,649 references. After limiting these to shoulder-specific references and eliminating duplicates 100 references were further searched for exact matching to the question of the role of resection arthroplasty in the management of acute PJI (subacute or chronic PJI). All full papers, reviews and abstracts in English between 1990 and 2018 were examined, and those reporting the indications and outcomes of resection (excision) arthroplasty of the shoulder were examined further. Personal searches of PubMed archives were performed by both authors using the same criteria, and their searches were compared. The bibliographies of two recent reviews (one specifically examining the question of resection, the value of spacers and one-and two-stage revision arthroplasty in subacute or chronic PJI [1], the other a more general review [2]) were examined for further references and cross-checked with the first enquiry and the personal searches.

No manuscripts were identified which reported on resection shoulder arthroplasty for acute PJI.

Conclusion

The available literature has no evidence pertaining to resection arthroplasty in acute shoulder PJI to provide guidance on this question.

Authors: José M. Mora, Simon Lambert

QUESTION 2: Is there a role for resection shoulder arthroplasty in the management of subacute or chronic periprosthetic joint infection (PJI)?

RECOMMENDATION: The available literature does not support specific indications for resection arthroplasty for subacute or chronic shoulder PJI with sufficient quality information to provide guidance. Resection arthroplasty is an acceptable salvage treatment to eradicate shoulder PJI when revision to a definitive implant is considered too risky due to patient medical co-morbidities or technical complexity.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 95%, Disagree: 0%, Abstain: 5% (Unanimous, Strongest Consensus)

RATIONALE

There are no prospective studies or randomized trials on this topic, and all published reports are retrospective case series. In addition, many of these case series include no other cohort to directly compare against any other form of treatment strategy for infected shoulder arthroplasty. The available literature is further limited by the fact that all published series examine outcomes using a variety of methods: (a) pain relief, recorded either as a subset of a score, e.g., the Constant-Murley (CMS) or American Shoulder and Elbow Surgeons (ASES) scores, or as a visual analog scale (VAS); (b) function, recorded either as a subset of a score, or by direct description; (c) management of infection, recorded as either "eradicated," "recurrent" or "persistent" (with no clear definition on how these categories was diagnosed/confirmed).

The systematic review of management strategies for shoulder PJI by George et al. [1] found 8 papers (total number of cases, 83) relating to the use of resection arthroplasty. The number of cases reported per series varied between 5 and 21 with a mean duration of follow-up of post-resection 39.8 months (standard deviation 20.8), minimum 19.2 (9.4), maximum 102.6 (41.9). The number of infections considered eradicated was 72/83 (86.7%) with no difference (statistical or clinically meaningful) in infection eradication observed between resection, single-stage, two-stage and permanent spacer arthroplasty. Preoperative and postoperative functional scores were incompletely reported. Single-stage revision cases had better preoperative scores than other groups, and better outcomes. It should be noted that patients reported worse functional scores (CMS) after surgery than before surgery, particularly for resection arthroplasty. There was no consistency in the choice or duration of antibiotic administration after surgery. Importantly, the authors pointed out that the limited quality of the available literature meant that it was not possible to provide a conclusion concerning the indication for one modality over another if the aim of intervention was to eradicate infection while optimizing the functional outcome for patients.

When reviewing the available literature, it should be noted that the majority of PJI for which resection is reported as an outcome are reverse total shoulder arthroplasties [2–4]. It is not clear whether this relates to the more challenging reconstructions often encountered after revision reverse total shoulder arthroplasty (TSA) or perhaps the nature of the reverse TSA patient population who tend to have more medical comorbidities and lower functional demands.

Patient outcomes including eradication of infection, pain relief and function were reported using variable standards. The concept that resection arthroplasty carries the advantage of being "one final surgery" should be tempered by the results showing that, on average, two debridements were required for infection to be clinically eradicated (mean follow-up 20 months) [5]. Braman et al. [5] showed that in their series of seven patients, while the functional scores were generally poor, all patients were able to perform activities between the mouth, opposite axilla and perineum and were satisfied with the outcome. Other authors, however, have shown that patient satisfaction is poor overall. Rispoli et al. reported one-third of cases falling into the lower third of categories for satisfaction, and 16 of 18 cases having an unsatisfactory outcome by Neer criteria [6]. If preoperative impairment was not substantial (defined as a CMS of greater than 30) then there was no significant improvement after surgery [2]. The same authors considered that reimplantation (whether one- or two-stage) delivered better functional outcomes than resection arthroplasty [2]. Zavala et al. (2012) concluded that resection was inferior to a debridement, antibiotics, irrigation and implant retention (DAIR) strategy in providing for function without increasing the risk of persistent or recurrent infection at a minimum of 12 months follow-up, while also commenting that implant retrieval lead to (potentially) revision-limiting bifocal bone loss [7]. DeBeer et al. recommended resection be indicated for the elderly with PJI and with lower functional expectations [8]. A single comparative study comparing resection with staged reimplantaion demonstrated that there was benefit for range of motion if a staged reimplantation could be safely undertaken with no increased risk of persistent or recurrence of infection [9]. This study was presented at the American Academy of Orthopaedic Surgeons (AAOS) and does not appear to have been published elsewhere. Resection arthroplasty for subacute or chronic PJI may some provide pain relief in approximately one-third to one-half of cases [3,6,7,10–12].

There are some technical and prognostic factors which may effect patient functional outcome and satisfaction. Retention of the tuberosities appears useful for function, possibly by reducing the tendency for proximal humeral migration [12]. In addition, there is some debate regarding how an antibiotic spacer may compare with resection alone with respect to eradication of infection and function. Verhelst et al. reported that use of a spacer (permanent

TABLE 1. Articles specifically concerning resection arthroplasty in shoulder PJI, with details as noted

		5 EAS		20.6	1		6				

NB: many data are incomplete since not all ideal data were recorded by the authors (see [6]). In three studies there are comparison cases of explantation and antibiotic spacer (EAS) and explantation alone (E) [1,13,14,16].

or temporary) did not appear to compromise eradication of infection but also did not necessarily confer benefit for function or pain relief postoperatively [13]. In contrast, Ghijselings in a comparative series evaluating resection with resection plus antibiotic-impregnated spacer reported a differential benefit for spacer with regard to domestic activities, but overall functional scores and pain relief were no different [14]. In the setting of bilateral pathology, Ueda et al. concluded there is improved function for domestic activities with bilateral retained antibiotic spacers when compared with historical reports of resection arthroplasties for PJI [15].

In summary, the functional result is relatively poor, but the eradication of infection is quite good (86.7%), especially considering that in these non-randomized studies patients with resection arthroplasty are likely frail and/or have difficult to treat pathogens [1]. It remains unclear whether a resection arthroplasty is preferred versus a retained antibiotic-impregnated cement spacer, with some studies suggesting a modestly better functional result with the spacer. Resection arthroplasty is an acceptable salvage treatment when revision to a definitive implant is considered too risky due to patient medical co-morbidities or technical complexity of revision surgery.

Search Strategy

A request via the Royal Society of Medicine Library utilising ProQuest Dialog, searching Embase and Medline archives with search terms (excision arthroplasty) OR (resection arthroplasty) AND (acute periprosthetic infection) OR (chronic periprosthetic infection) OR (subacute periprosthetic infection) yielded 1649 references. After limiting these to shoulder-specific references and eliminating duplicates, 100 references were further searched for exact matching to the question of the role of resection arthroplasty in the management of subacute/chronic PJI (SA/C PJI). All full papers, reviews and abstracts in English between 1990 and 2018 were examined, and those reporting the indications and outcomes of resection (excision) arthroplasty of the shoulder were examined further.

Personal searches of PubMed archives were performed by both authors using the same criteria, and their searches were compared. The bibliographies of two recent reviews (one specifically examining the question of resection, the value of spacers and one-and two-stage revision arthroplasty in subacute/chronic PJI [1], the other a more general review [17]) were examined for further references and cross-checked with the first enquiry and the personal searches. This strategy was compared with that of the most useful review [1] for completeness.

In Stevens et al. [16], there were seven patients available – eight cases (four explantation and four explantation and antibiotic spacer). In mobility there were three cases with data not available. In relation to "failed," there was only one case following explantation alone, which equates to 25% as a proportion of the group, or 12.5% as a proportion of all cases in this series.

3.7. TREATMENT: REVISION

Authors: Mandeep Virk, Iván Encalada, Gerald Williams

QUESTION 1: Is there a role for an antibiotic spacer for the treatment of shoulder periprosthetic joint infection (PJI)?

RECOMMENDATION: An antibiotic loaded cement spacer may be used as part of a shoulder two-stage exchange arthroplasty for local delivery of high concentration of antibiotics. An antibiotic loaded cement spacer may be used as a definitive/permanent treatment option in select cases.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Antibiotic loaded cement spacers can be used in the management of infected shoulder arthroplasty [1–4]. The antibiotic loaded cement spacer delivers antibiotics to the local tissues, eliminates dead space, maintains soft tissue tension and shoulder function and is used for these reasons as a temporary spacer in two-stage reimplantation for infected shoulder arthroplasty [2,3]. Less commonly, it can be considered as a permanent/definitive spacer if the patient declines further surgery or if the patient is not a good surgical candidate for the second stage of two-stage reimplantation (e.g., sick patient, significant bone loss) [5–8].

The role of antibiotic loaded cement spacer in shoulder PJI has been studied previously in retrospective cohort studies (Table 1). An antibiotic loaded cement spacer is indicated as a temporary spacer in the two-stage treatment of shoulder PJI in conjunction with intravenous antibiotics [2,3]. However, use as a definite/permanent spacer has also been described as a treatment for patients who are a high surgical risk or refuse second stage of two-stage treatment [5–7]. Jawa et al. reported a retrospective review of 28 patients with infected shoulder arthroplasty who were managed with antibiotic loaded cement spacer [2]. Sixteen patients underwent a two-stage operation, and twelve patients declined second stage procedure. Five patients had recurrence of infection (18%), and 5 patients had severe pain (18%) at final follow up. Complications with the use of cement spacer included dislocation (1 patient) and fracture (3 patients). Torrens et al. reported a culture positive rate of 13.6% (3 shoulders) from 22 antibiotic loaded cement spacers retrieved during second stage reimplantation [9]. In contrast to studies by Jawa et al. and Torrens et al., other investigators have reported lower rates of recurrence of infection with antibiotic loaded cement spacer use. Pellegrini et al. reported no recurrence of infection with a definitive antibiotic spacer in a cohort of 19 low demand, elderly subjects who had infected shoulder arthroplasties [6]. At a mean follow up of 8 years, all patients reported satisfactory subjective and objective outcomes. One patient had glenoid osteolysis with no adverse effect on functional outcome. Levy et al. retrospectively reviewed outcomes in 9 patients with infected shoulder arthroplasty who elected to not have the second stage reimplantation [7]. These patients had acceptable function with their antibiotic spacers at a mean follow up of 25 months. There was no recurrence of infection (0%) and only one patient (11%) was unsatisfied with the results. Mahure et al. reported no recurrence of infection (0%) in a retrospective case series of patients with shoulder PJI who received an antibiotic loaded cement spacer as definitive treatment after first stage of the two-stage treatment [5,10]. In a retrospective study, Romano et al. reviewed 44 patients with infected shoulder arthroplasty of which 32 patients had treatment with a temporary or permanent antibiotic loaded spacer [11]. There was one recurrence of infection in the definitive spacer group. Lee et al. used an antibiotic loaded cement spacer for the first stage implantation in 12 patients with infected shoulder arthroplasty. All patients received intravenous antibiotics followed by the second stage treatment [12]. There was no recurrence of infection (0%) at mean follow up of 41 months. Improved functional outcomes with the use of antibiotic loaded cement spacer was reported by Jerosch et al. in a retrospective review of 10 patients with shoulder PJI [13]. Patients were able to perform physical therapy with the antibiotic spacer in situ, and 8 patients underwent second stage with no reported recurrence of infection.

There is no consensus on the optimal class of antibiotics to be used in spacer preparation. Heat stable antibiotics (vancomycin, gentamycin and tobramycin) have been used alone or in combination. Spacer design and patient-specific anatomic features have also been studied with regards to infection clearance and patient satis-

TABLE 1. Studies examining the role of antibiotic loaded cement spacer in treatment of infected shoulder arthroplasty

Study	Number of Patients / Shoulders (n) and Follow-up (FU)	Antibiotics Used in the Cement Spacer	Spacer Role	Recurrence of Infection and Complications Associated with Spacer
Jerosch and Schneppenheim, 2003	n = 10 FU:6-30 mos (range)	No information	Temporary: 8 Permanent: 2	Recurrence: 0%
Themistocleous et al., 2007	n = 4 FU:22 mos	Tobramycin Vancomycin	Temporary: 2 Permanent: 2	Recurrence: 0%
Coffey et al., 2010	n = 16 FU:20.5 mos	Gentamicin	Temporary: 12 Permanent: 4	Recurrence: 0%
Jawa et al., 2010	n = 28 FU= 27.6 mos	Tobramycin Vancomycin	Temporary: 16 Permanent: 12	Recurrence: 5 (18%) Dislocation: 1 (3.5%) Fracture of spacer: 3 (11%)
Stine et al., 2010	n = 30 FU: 2.4 yrs	Tobramycin Vancomycin	Temporary: 18 Permanent: 15	Recurrence: 0%
Romano et al., 2012	n = 32 FU:2.4 yrs	No information	Temporary: 17 Permanent: 15	Recurrence: 3% (one in permanent group)
Levy et al., 2014	n = 9 FU:25 mos	Tobramycin Vancomycin	Permanent	Recurrence: 0%
Mahure et al., 2016	n = 9 FU:4 yrs	Tobramycin Vancomycin Gentamycin	Permanent	Recurrence: 0% Glenoid erosion: 2 (22%) Periprosthetic fracture: 1 (11%)
Pellegrini et al., 2017	n = 19 FU:8 yrs	Gentamycin, Clindamycin, Vancomycin	Permanent	Recurrence: 0% Glenoid osteolysis (1; 5.3%)
Padegimas et al., 2018	n = 37 FU:4 yrs	Tobramycin Vancomycin	Temporary	Spacer revision: 1 (2.7%) 6 positive cultures at second stage but no clinical signs of infection
Lee et al., 2018	n = 12 FU:40.8 mos	Vancomycin	Temporary: 9	Recurrence: 0%
Torrens et al., 2018	n = 21	Tobramycin	Temporary	Revision of spacer: 1 3 Positive cultures at second stage (13.6%)

faction. Padegimas et al. retrospectively compared stemless and stemmed antibiotic spacers in a cohort of 37 patients with shoulder PJI [14]. They found no difference between the two types of spacers with respect to their ability to control infection and the percentage transition (70% in both groups) to the second stage of a two-stage procedure for infected shoulder arthroplasty. There is insufficient date to compare handmade versus commercial premade antibiotic loaded cement spacers.

An antibiotic loaded cement spacer is a reasonable treatment option as a temporary antibiotic spacer in conjunction with intravenous antibiotics for the two-stage treatment of shoulder PJI. The majority of studies report no recurrence of infection after revision to second stage. Use of an antibiotic loaded cement spacer as a definitive/permanent treatment can be considered for a low demand, debilitated patient who is a poor surgical candidate for second stage reimplantation or in cases where patient refuses second stage surgery. There is low rate of infection (5%) with acceptable functional outcome, but glenoid osteolysis is a concern with the use of cement spacer as a definitive treatment. There is no consensus on the ideal class of antibiotic (vancomycin versus aminoglycosides) to be used in cement spacers. There is insufficient data to compare hand-made versus commercial premade antibiotic spacers.

Search Methods

In order to establish guidelines for the use of an antibiotic loaded cement spacer in infected shoulder arthroplasty, a systematic review of literature on PubMed and Embase was performed of all English

literature till January 2018 to query, "(shoulder OR 'upper extremity') AND (arthroplasty OR replacement) AND (infection OR infected) AND (PROSTALAC OR ANTIBIOTIC SPACER). After excluding duplicates, a total of 34 articles were screened, and 16 studies focusing on use of an antibiotic loaded cement spacer as a temporary or permanent spacer were extracted for further review. After applying final exclusion ("one-stage revision," "antibiotic suppression") and inclusion criteria, a full text review of the articles was conducted, and 12 articles were selected for final analysis. All the articles evaluated the role of antibiotic loaded cement spacer for the treatment of shoulder PJI [2–14].

QUESTION 2: What are the indications for one- versus two-stage exchange arthroplasty in the management of acute shoulder periprosthetic joint infection (PJI)?

RECOMMENDATION: Unknown. Single-stage exchange for shoulder PJI had a statistically significant lower reinfection rate and lower complication rate than two-stage exchange in aggregate; however, no studies exist directly comparing these treatments for acute shoulder PJI.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 96%, Disagree: 4%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

A comprehensive literature review was performed to identify all studies on revision shoulder arthroplasty for PJI. Terms used for the search included "infection," "shoulder replacement," "arthroplasty," "1-stage," "2-stage," "reimplantation," "prosthetic-related infection" and included "resection," "spacer" or "exchange" among others using PubMed, Scopus and Embase through February 2018. Inclusion criteria for our systematic review were all English studies (Level I-IV evidence) that reported on single or two-stage revision, infection eradication for revision shoulder arthroplasty with a minimum follow up of twelve-months and minimum of five patients for analysis. Exclusion criteria for our review were all non-English studies, papers that exclude single or two-stage exchange, review papers, case reports or technique articles without outcome data. Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) criteria were applied. Title and abstract screening was conducted through 248 results; full text review was conducted with 66 results and produced 31 articles that met inclusion and exclusion criteria for review.

Shoulder PJI is a devastating complication with significant morbidity. The incidence of PJI after primary shoulder arthroplasty has reported ranges of 1-4% and up to 4-15% after revision arthroplasty [1,2]. Historically, treatment for shoulder PJI has been influenced by evidence from hip and knee arthroplasty infection management experience [3,4]. Two-stage exchange arthroplasty with implant removal, irrigation and debridement (I&D), and insertion of antibiotic spacer, followed by delayed re-implantation has been suggested as gold standard for shoulder PJI [3]. However, single-stage exchange has also been advocated to achieve similar infection control with a single surgery [5–7]. The purpose for this review was to understand the roles of single-stage and two-stage exchange revision in the setting of acute shoulder PJI and compare the outcomes.

In this review, varying studies collected demographics, timing of infection, associated pathogens, surgical treatment, antibiotics, eradication rate for infection, surgical complications and functional outcomes with two-year follow-up minimum. We identified 12 articles that evaluated one-stage exchange and 27 articles that evaluated two-stage exchange.

While the definition and diagnosis of shoulder PJI is beyond the scope of this review, it should be noted that the majority of papers reported using preoperative laboratory values (including elevated white blood cell count, C-reactive protein (CRP) and/or erythrocyte sedimentation rate (ESR)), as well as joint aspiration and/or intra-

TABLE 1. Reinfection and complication

One-Stage	Patients	Reinfection %	Pathogens	Constant Score	Complications
12 Papers	161 Total	5.6% Reinfection	72 P. acnes	49.1	12.70%
	6 Acute	$p < 0.05$	29 CoNS	44 Patients	79 Patients
	13 Subacute		20 MSSA	$p < 0.11$	$p < 0.05$
	8 Chronic		3 MRSA		
Two-Stage	**Patients**	**Reinfection %**	**Pathogens**	**Constant Score**	**Complications**
27 Papers	325 Patients	11.4%	88 P. acnes	51.1	21.90%
	47 Acute	$p < 0.05$	64 CoNS	102 Patients	205 Patients
	46 Subacute		33 MRSA	$p < 0.05$	$p < 0.05$
	74 Chronic		56 MSSA		

operative cultures with bacterial growth to arrive at the diagnosis of shoulder PJI. Clinical findings, such as draining sinus, erythema or swelling, were inconsistently reported. There was inconsistent reporting and definition of the timing of infection as acute, sub-acute or chronic. The majority of studies report timing of infection using terms from Sperling et al. and Strickland et al. with acute meaning < 3 months, sub-acute meaning 3-12 months and chronic > 12 months [8, 9]. There was relatively consistent reporting of the pathogens found either pre- or intraoperatively. *Cutibacterium acnes* (*C. acnes*) was the most common organism identified with 160 cases or 32.9% of all cases followed by *Coagulase-negative Staphylococcus* (CoNS) with 93 cases or 19.1% [2,4,7–15]. There were 57 reported cases of poly-microbial infections and 27 cultures that resulted in no growth [4,7,10–12].

To address the stated question, we reviewed data on acute shoulder PJI pertaining to infection eradication using single or two-stage exchange and additional functional outcomes, which are summarized in Tables 1 and 2. In total, 161 cases were identified as treated with single-stage revision and 325 cases of two-stage revision. The majority of studies report timing of infection but few report the success of treatment with either single or two-stage exchange based on timing of infection. Beekman et al. performed analysis on three cases of acute PJI treated with single-stage exchange showing no cases with reinfection [5]. Two additional studies with a total of three cases of acute PJI found no patients had reinfection [6,10]. With two-stage exchange, Buchalter et al. [16] described 1 case of acute PJI that had no reinfection. Another study reported 1 case of acute PJI that failed treatment with two-stage exchange and had persistent infection. In total, four studies reported no cases of reinfection with two-stage exchange with specific analysis of an acute PJI subgroup.

This review has highlighted gaps that exist in current literature. All studies identified were retrospective and thus have substantial selection bias. While the findings in aggregate suggest single-stage exchange is a viable option for PJI, the numbers were small, and there are no studies that control for various risk factors and selection biases such as the particular pathogen, its antibiotic resistance profile, timing of infection or diagnostic features such as obvious clinical findings of infection. Furthermore, there are insufficient numbers of studies that provide analysis for treatment of acute

TABLE 2. Functional outcome

One-Stage	Neer (total)	ASES (mean)	SST (mean)	DASH	FF (mean)	ABD (mean)	ER (mean)

QUESTION 3: What are the indications for one- versus two-stage revision in subacute or chronic shoulder periprosthetic joint infection (PJI)?

RECOMMENDATION: The indications for one-stage versus two-stage exchange are unclear at this time. The pooled data demonstrate one-stage exchange to be superior to two-stage exchange, but this may be a result of selection bias and other factors.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 96%, Disagree: 0%, Abstain: 4% (Unanimous, Strongest Consensus)

RATIONALE

A comprehensive literature review was performed to identify all studies on revision shoulder arthroplasty for periprosthetic joint infection (PJI). Terms used for the search included "infection," "shoulder replacement," "arthroplasty," "1-stage," "2-stage," "reimplantation," "prosthetic-related infection" and included "resection," "spacer" or "exchange" among others using PubMed, Scopus and Embase through February 2018. Inclusion criteria for our systematic review were all English language studies (Level I-IV evidence) that reported on single or two-stage revision, infection eradication for revision shoulder arthroplasty with a minimum follow up of twelve-months and minimum of five patients for analysis. Exclusion criteria for our review were all non-English language studies, papers that exclude single or two-stage exchange, review papers, case reports or technique articles without outcome data. Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) criteria were applied. Title and abstract screen was conducted of 248 results and a full text review of 66, identified 31 articles that met inclusion and exclusion criteria for final review.

The purpose for this review was to understand and compare the role of single-stage and two-stage exchange for the treatment of shoulder PJI. Two-stage exchange arthroplasty with implant removal, irrigation and debridement (I&D), insertion of antibiotic spacer, antibiotic treatment, followed by re-implantation has been suggested as gold standard for treatment of shoulder PJI [1]. Varying studies collected demographics, timing of infection, associated pathogens, surgical treatment, antibiotics, eradication rate for infection, surgical complications and functional outcomes with two-year follow-up minimum. We identified 12 articles that evaluated one-stage exchange and 27 articles that evaluated two-stage exchange. The majority of papers reported preoperative laboratory values to diagnose PJI based on elevated white blood cell count, C-reactive protein and/or erythrocyte sedimentation rate. Clinical findings such as draining sinus, erythema or swelling were inconsistently reported. Most studies reported the number of joint aspirations performed and resulted positive with microbial growth. Although there was inconsistent reporting of timing of infection, the majority of studies that reported timing of infection used terms from Sperling et al. and Strickland et al. with acute meaning < 3 months, sub-acute meaning 3-12 months and chronic > 12 months [2,3]. There was consistent reporting of the pathogens found either pre- or intraoperatively. *Cutibacterium acnes* (*C. acnes*) was the most common organism identified with 160 cases followed by *Coagulase-negative Staphylococcus* (CoNS) with 93 cases [2,4–14]. There were 57 reported cases of polymicrobial cases and 27 cultures that resulted in no growth [4–8].

To address the stated question, we reviewed studies in aggregate for sub-acute and chronic infection when treated with either single

TABLE 1. Reinfection and complications for single stage exchange

Cases	Reinfection Rate	Pathogens	Constant Score (mean)	Complication Rate
161 Total 13 Subacute 8 Chronic	5.6 % ($p < 0.001$)	72 *C. acnes* 29 CoNS 20 MSSA 3 MRSA	49.1 ($p < 0.11$)	12.7 % ($p < 0.001$)

CoNS, Coagulase-negative *Staphylococcus*; MSSA, methicillin-susceptible *Staphylococcus aureus*; MRSA, methicillin-resistant *Staphylococcus aureus*

TABLE 2. Reinfection and complications for two-stage exchange

Cases	Reinfection Rate	Pathogens	Constant Score (mean)	Complication Rate
325 Total 46 Subacute 74 Chronic	11.4 % ($p < 0.001$)	88 *C. acnes* 64 CoNS 33 MSSA 56 MRSA	51.1 ($p < 0.05$)	21.9 % ($p < 0.001$)

CoNS, Coagulase-negative *Staphylococcus*; MSSA, methicillin-susceptible *Staphylococcus aureus*; MRSA, methicillin-resistant *Staphylococcus aureus*

or two-stage revision summarized in Tables 1 and 2. Four studies directly compared revision success rate for shoulder PJI with single-stage exchange in sub-acute or chronic presentation. The reinfection rate was 12.5% for chronic cases and 5.3% for sub-acute cases [4,14,15]. Regarding two-stage exchange, three studies specifically reported success rates for either sub-acute or chronic shoulder PJI. Reinfection rate was 6.3% for chronic PJI and 29.4% for sub-acute PJI treated with two-stage exchange [2,4,15]. Several other studies reported the timing of infection but did not compare revision failure rates according to the subgroups of acute, sub-acute or chronic PJI groups. In aggregate, using a frequency-weighted mean, the reinfection rate was 5.6% for one-stage exchange compared to 11.4% for two-stage exchange, which was statistically significant ($p < 0.001$).

Analyses of complications related to single or two-stage exchange in acute, sub-acute or chronic infection were limited. In aggregate, all surgical complications reported include aseptic loosening, fracture, nerve palsy, dislocation and hematoma. Our systematic review found a 12.7% complication rate for single-stage exchange compared to a 21.9% complication rate for two-stage exchange, which was statistically significant. Although this finding suggests that patients undergoing two-stage exchange have 1.72 times the risk of intra- or postoperative complication, the analysis was not able to account for likely bias in the selection of treatment. The selection bias cannot be over-emphasized—it very well may be that cases with more severe infections were preferentially treated with two stage while less severe infections were treated with single-stage revision.

Frequency-weighted mean Constant Murley Score (CMS) was 49.1 for single-stage patients and 51.1 for two-stage exchange, which was similar to prior findings [7,15]. In the single-stage studies, a total of 57 patients had 78.2 degrees of FF; 42 patients had 52.4 degrees of abduction and 59 patients had 25.4 degrees of external rotation. Two-stage exchange papers reported 194 patients had 98.9 degrees of FF, 72 patients with 52.4 degrees of abduction and 144 patients with 29.2 degrees of external rotation. No studies compare the timing of infection and treatment with single or two-stage revision.

All papers identified are retrospective thus contain significant selection bias. While our findings in aggregate suggest single-stage exchange is a viable option for PJI, there are few studies that address reinfection associated with various risk factors such as pathogens, timing of infection or diagnostic features such as obvious clinical findings of infection. Thus, we cannot recommend using single-stage exchange in place of two-stage exchange for shoulder PJI without further investigation.

QUESTION 4: Is there a role for preoperative joint aspiration prior to reimplantation during two-stage exchange for shoulder periprosthetic joint infection (PJI)?

RECOMMENDATION: There is a dearth of information on the role of preoperative joint aspiration prior to second stage revision after treatment of shoulder PJI. Furthermore, several studies have pointed to the high incidence of "dry taps" and false negative cultures from joint aspirates. Thus, there is little evidence in support of routine preoperative aspiration prior to second stage reimplantation.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 88%, Disagree: 4%, Abstain: 8% (Super Majority, Strong Consensus)

RATIONALE

A systematic review of the published literature was performed on PubMed using the search terms Shoulder (Title) AND [Periprosthetic OR reverse shoulder OR total shoulder OR arthroplasty OR replacement OR prosthesis (Title/ Abstract)] AND [Infection OR infected OR septic OR sepsis OR PJI OR propionibacterium OR acnes OR staphylococcal OR staphylococcus OR second stage OR OR staged OR revision OR spacer OR two-stage OR two stage OR reimplantation OR purulent OR purulence OR sinus tract (Title)]. This search yielded 255 articles. All titles were reviewed and articles with potential relevance had their abstracts reviewed. In total, with full texts reviewed, 31 articles where considered relevant to this topic in some fashion. Articles were deemed relevant if they included any aspirate information on patients with shoulder arthroplasties. These articles were used to make the recommendation. The reference lists of the included articles were further searched to identify other references that may have been omitted.

Controversy remains regarding the best surgical treatment of shoulder PJI. The literature documents interventions including open debridement with component retention or liner exchange, single stage re-implantation comprising removal of all components and immediate re-implantation after thorough debridement and lavage, resection arthroplasty after removal of all components and two-stage re-implantation. The latter involves a first stage that includes removal of all components followed by debridement, and in many cases insertion of an antibiotic impregnated polymethylmethacrylate cement spacer for local antibiotic delivery and to preserve soft tissue tension. The patient is then treated with intravenous (sometimes followed by oral) antibiotics and monitored, typically with serial serologic evaluation, prior to the second surgery (second stage revision) at which time the spacer is removed and new components are re-implanted.

In patients who undergo two-stage re-implantation for shoulder PJI, shoulder joint aspiration or arthrocentesis prior to second stage revision is one method to evaluate for persistent infection after the first stage explantation and subsequent antibiotic treatment. The aspirate can be sent for cultures, leukocyte cell count and differential, and also for analysis of biomarkers such as alpha-defensin. Shoulder aspiration is an established diagnostic tool and is commonly used (although not routinely) as part of the workup of PJI, including shoulder PJI.

However, there is little published information on the use of shoulder aspiration prior to second stage revision. In addition, there is no data documenting an advantage of shoulder aspiration over no aspiration or over any alternative diagnostic tool for shoulder PJI. Sabesan et al. reported that 12 of 17 patients had preoperative aspiration prior to the first stage. re-implantation [1]. Fluid was obtained for culture in 10 and 6 had positive cultures. Prior to the second stage the patients were ruled out for persistent infection with preoperative erythrocyte sedimentation rate, C-reactive protein (CRP), white blood cell (WBC) count and a negative preoperative aspirate. One of the 17 patients had intraoperative frozen section that was positive for acute inflammation and had repeat treatment for infection. Two small case series studies recommend preoperative aspiration prior to considering second stage revision, but only in cases with persistently elevated CRP and WBC [2,3]. Buchalter et al. have described their algorithm for two-stage re-implantation for shoulder PJI but do not mention shoulder aspiration as a factor in their timing of second-stage revision [4]. Patients were offered a second stage reimplantation if they had no clinical signs of infection and their inflammatory markers normalized.

If shoulder joint aspiration is considered in the evaluation for PJI, it is typically recommended to hold antibiotics for at least 14 days prior to aspiration [2,3,5]. It is also important to note that a negative culture of fluid aspirate or dry aspirate is not diagnostic of a resolved infection based on studies that include preoperative shoulder aspirations [5,6].

QUESTION 5: Is there a role for pre-reimplantation open or arthroscopic tissue biopsy in the evaluation during two-stage exchange of shoulder periprosthetic joint infection (PJI)?

RECOMMENDATION: Unknown. There is one level IV study suggesting that open biopsy prior to second-stage revision for shoulder PJI can identify patients with persistent infection who may benefit from subsequent repeat irrigation and debridement (I&D) prior to second stage reimplantation.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

PubMed and Embase were searched from 1980 to January 2018 to identify studies evaluating preoperative open or arthroscopic tissue biopsy prior to second stage revision shoulder arthroplasty after treatment of shoulder PJI. A secondary search of the references of included studies was also conducted. One article was selected for inclusion. Articles regarding hip and knee arthroplasty were excluded.

Zhang et al. reported a level IV case series in which they performed open biopsy prior to second stage revision for treatment of shoulder PJI [1]. Eighteen patients with shoulder PJI between 2005 and 2012 were included. Patients were treated with a standard protocol involving I&D, removal of implants, antibiotic spacer placement and antibiotic therapy based on culture results for six weeks based on infectious disease service recommendations. At a minimum four weeks after completion of antibiotics, patients were re-evaluated to ensure no clinical symptoms of infection were present and erythrocyte sedimentation rate/ C-reactive protein (ESR/CRP) had normalized. At this point, all patients underwent open biopsy via deltopectoral incision to obtain at least three soft tissue and bone cultures from tissue adjacent to the bone-antibiotic spacer interface. If cultures were negative for 7 to 14 days, patients underwent reimplantation. If cultures were positive, patients instead underwent repeat I&D with antibiotic spacer exchange and the protocol was repeated.

Zhang et al. found that 4 of 18 patients (22%) had positive cultures from the open biopsy indicative of persistent infection with a 38% persistent infection rate for individuals infected with *C. acnes*. One patient had positive cultures again on second open biopsy and underwent a second spacer exchange prior to finally obtaining a negative third biopsy and undergoing reimplantation. *C. acnes* was the most common pathogen, present in 44% of index shoulder PJIs. Among persistent infections, 3 of 4 patients (75%) had *C. acnes*, and the patient requiring two spacer exchanges had *C. acnes* on each occasion. At a mean of 24 month follow-up (range 12 to 36 months), all 18 patients were reimplanted (2 hemiarthroplasty, 1 total shoulder arthroplasty (TSA), 15 reverse total shoulder arthroplasty (RTSA)) and noted to be clinically infection-free with an average American Shoulder and Elbow Surgeons (ASES) score of 71.

This study is limited in its level IV design and small sample size. Furthermore, patients undergoing two-stage revision had variable index procedures from which they developed shoulder PJI, including one open reduction internal fixation (ORIF) proximal humerus fracture, three hemiarthroplasties, six rotator cuff repairs, five TSAs and three RTSAs. There is no comparison group of patients who did not undergo open biopsy, and no comparison to alternative methods such as shoulder aspiration or arthroscopic biopsy.

The role of open or arthroscopic biopsy prior to reimplantation during a two-stage exchange arthroplasty remains unclear.

PART IV

SPINE

Prevention

1.1. PREVENTION: GENERAL PRINCIPLES

Authors: Steven Schmitt, Christopher Kepler

QUESTION 1: What can one do if an inadvertent contamination during instrumented spine surgery occurs?

RECOMMENDATION: There is no data to support a particular strategy in preventing infection after inadvertent contamination of spinal implants.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Left uncovered in the operating suite, spinal implants can become contaminated within 30 minutes [1]. There are no human data to support a particular algorithm for management of inadvertent contamination. In animal studies, tobramycin powder has been shown to reduce infection in contaminated spine surgery and vancomycin powder has been shown to reduce infection in contaminated knee surgery [2,3]. At least one suggests that management of inadvertent contamination should be individualized to the clinical situation and stage of surgery, and many surgeons are reluctant to proceed with implant surgery if contamination has occurred. Some experts recommend intraoperative irrigation with solutions containing antibiotics, without supporting data (personal communication).

Author: Maja Babic

QUESTION 2: How should spine surgery patients with postoperative diarrhea be managed?

RECOMMENDATION: Diarrhea can be managed in a standard approach with careful attention to the surgical site.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 93%, Disagree: 0%, Abstain: 7% (Super Majority, Strong Consensus)

RATIONALE

Postoperative diarrhea poses a risk of contaminating the surgical incision. Maintaining a clean and dry surgical site is crucial. Postoperative diarrhea is generally self-limiting but infectious etiologies, especially *C. difficile*, are particularly concerning in the inpatient setting and should be ruled out. After infectious causes are ruled out, a standard approach should be implemented to address diarrhea including discontinuing potentially inciting medication (antibiotics), increasing fiber content and using antisecretory (i.e., bismuth subsalicylate) and antimotility (i.e., loperamide) agents. A balanced electrolyte rehydration should also be utilized. The use of probiotics and prebiotics can be used in cases of post-antibiotic-associated illness [1].

1.2. PREVENTION: ANTIMICROBIALS

Authors: Alexander Montgomery, Rajesh Mangattil

QUESTION 1: Is there a role for oral antibiotics in the prevention of infection in patients with draining wounds following spinal surgery?

RECOMMENDATION: There is no reliable evidence for the use of prophylactic oral antibiotic therapy in patients with draining wounds after spine surgery.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 93%, Disagree: 7%, Abstain: 0% (Super Majority, Strong Consensus)

RATIONALE

The incidence of spinal surgical site infection (SSI) has been reported to be from 0.7–16% [1–3]. Surgical drains are used in spine surgery to avoid the risk of a hematoma formation leading to potential neurological deficit [4]. Drains retained for a longer period have been shown to have a higher rate of bacterial contamination [5]. However, not using a drain has been found to be associated with the development of late-onset SSI [6,7]. Therefore, the use of drains decreases wound drainage and consequently decreases infection rates [8,9]. Prophylactic antibiotic cover for 24 hours has now become a standard of care following orthopaedic procedures [10].

Since the first systematic review on prophylactic measures against spinal SSI was published by Brown et al. in 2004 [11], there has been a considerable increase in the preventive strategies documented in the spine literature. However, many studies are of lower methodological quality with significant heterogeneity [12].

There was only one prospective randomized study showing no significant difference in the infection rates between patients receiving prophylactic antibiotic coverage for 24 hours or for the entire duration that the drain was in place. This study was on thoracolumbar fractures. It was not clear if the antibiotic cover was administered orally or parenterally [13]. In a review of 560 cases of closed suction drainage in single level lumbar decompressions, Kanayama et al. did not report on the use of prophylactic oral antibiotics [14]. Similarly, a 2018 systematic review by Yao et al. identified 11 randomized controlled trials (RCTs), 51 case-controlled studies (CCS) and 77 case series. They reported wide variations in the surgical indications, approaches and definitions of SSI. They found strong evidence that closed-suction drainage does not affect SSI rates, but had no mention of the use of prophylactic oral antibiotic therapy [15].

There were many studies that evaluated the risk factors for wound complications following spine surgery [16–18]. Past studies are archaic in nature with very little contribution or relevance to these authors. A staged treatment algorithm for spine infections did not specify or address the indication for oral antibiotics to prevent infection in draining wounds [19]. A recent retrospective study attributed the drain volume and time to the risk factors for SSI after lumbar surgery. There was no direct reference to the impact of oral or parenteral antibiotics in their study [13,20].

A systematic evidenced-based review included 36 observational studies involving 2,439 patients. However, these were non-interventional studies to evaluate the independent risk factors for patients developing SSIs following spine surgery [17]. In their systematic review and meta-analysis of wound drains in non-instrumented lumbar decompression surgery, Davidoff et al. included 5,327 cases who received drains. They found that the SSI rates were unaffected by the routine use of drains. However, none of these patients had prophylactic oral antibiotics [21]. Ho et al. reported a retrospective review of 70 patients who had undergone single-level lumbar discectomy. They suggested that surgical drains do not increase SSI risk and that drain tip cultures allow detection of postoperative infection at a very early stage. They found that this would lead to quicker initiation of antibiotic treatment [22].

Apart from a prospective randomized study that suggested no difference in the infection rates, there are no studies directly linking the role of oral antibiotics in the prevention of infection in patients with draining wounds following spine surgery [13]. Therefore, in the absence of reliable evidence, only a consensus recommendation can be made based on clinical opinion.

QUESTION 2: Is there a role for the addition of gentamicin to perioperative prophylactic antibiotics in spine surgery?

RECOMMENDATION: No, we recommend AGAINST the inclusion of gentamicin for perioperative prophylaxis in spine surgery. There is no data suggesting that the addition of gentamicin to systemic perioperative prophylactic antibiotic regimens decreases the rate of postoperative infections, and strong evidence showed that it is associated with harm (namely nephrotoxicity). The question of the use of local/topical gentamicin is unresolved.

LEVEL OF EVIDENCE: Strong

DELEGATE VOTE: Agree: 62%, Disagree: 15%, Abstain: 23% (Super Majority, Weak Consensus)

RATIONALE

The use of gentamicin to expand the gram-negative activity for perioperative antimicrobial prophylaxis in spine surgery has been considered for decades, yet positive outcomes data for this practice are lacking. Pons et al. reported on a randomized, blinded study of 826 patients undergoing neurosurgical procedures, including spine surgery, and found similar surgical site infection (SSI) rates for those assigned to ceftizoxime or vancomycin and gentamicin [1]. Ramo et al. reported on a multivariate analysis of 428 posterior spinal fusion patients and found that the addition of an aminoglycoside did not lower the SSI rate [2]. In a mixed population of more than 11,000 orthopaedic surgery patients treated over 5 years in the United Kingdom, Walker et al. noted no difference in SSI rates during a period when a combination of flucloxacillin and gentamicin was given for prophylaxis compared to one where co-amoxiclav was the prophylactic regimen of choice [3].

The association of aminoglycoside prophylaxis (even single-dose) for orthopaedic surgery and acute kidney injury (AKI) has now been well-documented. Dubrovskaya et al. reviewed more than 4,000 patients undergoing orthopaedic surgery, comparing those receiving a single dose of gentamicin combined with another antibiotic to those receiving non-aminoglycoside prophylaxis alone. Although for all patients the addition of gentamicin was not associated with AKI, gentamicin was associated with a statistically significantly higher rate of AKI for those undergoing spine surgery [4]. Bell et al. reported on a Scottish initiative where routine surgical prophylaxis was changed from cefuroxime to flucloxacillin and gentamicin (single-dose) between 2006 and 2010. Among 7,666 patients undergoing orthopaedic surgery, the gentamicin-containing regimen was associated with a 94% higher incidence of AKI [5]. Finally, in the previously-cited study by Walker et al., a change from routine prophylaxis with flucloxacillin and gentamicin to co-amoxiclav alone was associated with a 63% reduction in postoperative AKI [3].

Two meta-analyses on the association of gentamicin prophylaxis with nephrotoxicity have been published. Luo et al. compared the use of gentamicin and flucloxacillin to cefuroxime alone in studies of diverse surgery types. The risk of postoperative renal impairment was higher in the gentamicin group, especially for those undergoing orthopaedic surgery [6]. Srisung et al. analyzed 11 studies containing 18,354 patients comparing gentamicin versus non-gentamicin surgical prophylaxis regimens. Using random effects modeling, gentamicin prophylaxis in orthopaedic surgery was associated with a significantly higher risk of AKI (risk rate (RR) 2.99; 95% confidence interval (CI): 1.84, 4.88) [7].

Data regarding the use of topical or local wound gentamicin are limited. In a single-center study, van Herwijnen et al. reported a higher SSI rate for patients undergoing scoliosis surgery who received wound irrigation with gentamicin versus povidone-iodine [8]. On the other hand, Borkhuu et al. reported on 220 children undergoing spinal fusion and found a four-fold reduction in SSI for those treated with gentamicin-impregnated bone allograft [9]. Han et al. retrospectively analyzed data from 399 patients undergoing spine surgery. Among patients who had a gentamicin-impregnated collagen sponge applied to their wound, the SSI rate was 0.8%, versus 5% for those treated without the sponge [10]. At this time, however, given the variability in reported application methods for local gentamicin and the small number of patients studied, the routine use of topical gentamicin cannot be recommended.

QUESTION 3: Should prophylactic antibiotic prophylaxis be repeated during spine surgery? If so, when?

RECOMMENDATION: In most uncomplicated spinal procedures, a single preoperative dose of prophylactic antibiotics is sufficient. Prophylactic antibiotics should be redosed intraoperatively for procedures lasting longer than twice the half-life of the antibiotic, or if there is excessive blood loss (blood loss > 1,500 mL) in order to ensure therapeutic levels.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 93%, Disagree: 0%, Abstain: 7% (Super Majority, Strong Consensus)

RATIONALE

There are no randomized spine studies that compare the effectiveness of redosing prophylactic antibiotics during surgery to preoperative antibiotics alone. Therefore, this review was expanded to include other surgical subspecialties. Several major guidelines including those from the North American Spine Society (NASS), Infectious Disease Society of America (IDSA) and Surgical Infection Society (SIS) have made similar recommendations supported by pharmacokinetic data and retrospective studies [1,2]. Furthermore, the Centers for Disease Control and Prevention (CDC) recently noted that there is insufficient-quality evidence to make a recommendation regarding whether or not antibiotics should be redosed intraoperatively [3].

In a prospective study of 57 subjects undergoing elective surgery, an analysis of intraoperative serum cefazolin concentrations at approximately 3.5 hours after receiving a preoperative dose showed that antibiotic concentrations dropped below the minimum inhibitory concentration (MIC) for methicillin-susceptible *Staphylococcus aureus* (MSSA) and *Escherichia Coli* (*E. Coli*) [4]. Ohge and colleagues found that cefazolin concentrations had dropped below 80% of the MIC in the adipose tissue and peritoneum for multiple bacteria three hours after the preoperative dose was administered [5]. In a prospective study of 11 elective instrumented spinal procedures with a large expected blood loss, estimated blood loss (EBL) was found to have a strong negative correlation with cefazolin tissue concentrations ($r = -0.66$, $p = 0.5$). Based on the pharmacokinetic values, the authors recommended that procedures with an EBL greater than 1,500 mL should receive an additional dose of cefazolin [6].

In a retrospective study of 1,548 patients undergoing cardiac surgery, intraoperative redosing for procedures lasting greater than 400 minutes was shown to reduce the risk of surgical site infections (SSIs) (adjusted OR 0.44, 95% CI 0.23-0.86) [7]. Similarly, Scher et al. demonstrated that for surgeries longer than three hours, patients who were redosed with cefazolin intraoperatively had a lower SSI rate than those who only received preoperative cefazolin (6.1% vs. 1.3%, $p < 0.01$) [8]. In another retrospective review of 4,078 patients undergoing various general surgery procedures, cases with an EBL of greater than 500 mL or those that were not re-dosed intraoperatively during longer cases were associated with a higher rate of SSI [9].

Authors: Steven Schmitt, Christopher Kepler

QUESTION 4: Should vancomycin powder be applied to the wound in patients undergoing spinal surgeries? Are there any potential harms associated with this practice?

RECOMMENDATION: Yes. Evidence suggests that vancomycin powder applied to the wound during spinal surgery reduces the risk of infection. However, the majority of studies lack a control arm and it is not known if vancomycin powder is better than antiseptic agents. There is insufficient evidence for or against the potential harm associated with this practice.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 79%, Disagree: 14%, Abstain: 7% (Super Majority, Strong Consensus)

RATIONALE

Surgical site infection is a known risk of spine surgery with or without instrumentation, and gram-positive organisms are the most common pathogens in such infections. Many practitioners now apply vancomycin powder intraoperatively to reduce the risk of infection. Given concern for vancomycin's adverse effects and antimicrobial resistance, it is critical to consider a risk-benefit analysis of this practice.

A number of studies addressed the efficacy of vancomycin powder use in spine surgery. These have been the subject of several systematic reviews. Xie et al. reviewed 19 retrospective cohort studies and 1 prospective case study, with results suggesting benefit in all but 2 of these with an overall infection risk of 2.83-fold higher for patients not receiving vancomycin powder compared to those receiving it [1]. The authors pointed out study heterogeneity with regard to powder, drug dosage and exposure of bone graft and instrumentation to the drug, citing these as areas for future investigation. This trend toward benefit was confirmed in five other systematic reviews [2–6].

With regard to adverse effects, Ghobrial et al. performed a systematic review of 16 studies with 6,701 patients [7]. Of these, 1 patient developed nephropathy, 2 patients experienced hearing loss, 1 patient had an elevated vancomycin level and 19 patients developed culture-negative seroma. The authors highlighted the lack of in vivo evidence regarding vancomycin resistance. There was a trend toward gram-negative and polymicrobial infections among vancomycin powder recipients in one study [8].

Authors: Yvonne Achermann, John Koerner, Daniel Tarazona

QUESTION 5: What is the optimal perioperative antibiotic prophylaxis for patients undergoing spine surgery? What considerations should be made in cases of drug allergies?

RECOMMENDATION: The optimal prophylactic antibiotic for an uncomplicated spine surgery is a first- or second-generation cephalosporin given intravenously within 60 minutes of initial incision.

In patients with a history of anaphylactic reaction after use of beta lactams or in countries with a high rate of methicillin-resistant *Staphylococcal* infections, vancomycin in a weight-adjusted dose (15 mg/kg) should be used. Clindamycin 600 mg intravenously is an alternative to vancomycin.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 79%, Disagree: 7%, Abstain: 14% (Super Majority, Strong Consensus)

RATIONALE

Current literature supports the use of prophylactic antibiotics for spinal procedures with or without instrumentation to decrease the risk of surgical site infections (SSI), with a first- or second-generation cephalosporin being the antibiotic of choice [1–6]. In addition, clin-

ical guidelines set forth by the American Society of Health-System Pharmacists (ASHP), the Infectious Diseases Society of America (IDSA), the Surgical Infection Society (SIS), the Society for Healthcare Epidemiology of America (SHEA) and the North American Spine Society support the use of first-generation cephalosporins [1,7,8]. Although comparative studies to evaluate the optimal timing for preoperative antibiotic have not been conducted for spine surgery, it is well-established that intravenous cephalosporins given within 60 minutes before initial incision is effective [9,10].

In a comparative study evaluating the addition of vancomycin powder for posterior thoracic and lumbar spine surgery, Sweet et al. found that vancomycin powder reduced the rate of SSI compared to intravenous cephalexin alone (0.2% vs. 2.6%, $p < 0.0001$).

Regarding prophylaxis regiments combining antibiotic agents, randomized clinical trials exist which show a reduced rate of postsurgical infections if a combination of a cephalosporin and gentamicin or vancomycin and gentamicin is used, compared to placebo [11,12]. However, there are no studies available which compare combination regimens with the standard prophylaxis with cefazolin. A study by Pons et al. comparing ceftizoxime versus the combination prophylaxis with vancomycin and gentamicin found no decreased infection rate, but higher toxicity with the combination regimen [13].

There is no specific recommendation for adapted prophylaxis in obese patients in spine surgery. However, in periprosthetic joint infections, adaptation is discussed in patients with a weight more than 100 kg since infection rate was twice that in other patients [13–15].

Author: Dolors Rodriguez-Pardo

QUESTION 6: What are the optimal prophylactic antibiotics for patients with neurogenic bladder who are undergoing spine surgery?

RECOMMENDATION: The recommended standard perioperative antibiotic prophylaxis in spine surgery is cefazolin, but a broader-spectrum prophylaxis may be necessary in patient subpopulations more prone to acquiring surgical site infections (SSIs). In the case of neurogenic bladder, preoperative urine culture and individualized antibiotic prophylaxis are associated with a significant decrease in SSIs due to gram-negative bacilli (GNB).

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 79%, Disagree: 14%, Abstain: 7% (Super Majority, Strong Consensus)

RATIONALE

Prevention of SSI is of utmost importance in patients undergoing spine surgery, and perioperative antibiotic prophylaxis is a key measure to avoid this complication [1,2]. However, the superiority of one agent or schedule over any other has not been clearly demonstrated [1,2]. The recommended standard perioperative antibiotic prophylaxis in spinal surgery is cefazolin [1]. Isolated reports have shown that a broader-spectrum prophylaxis may be necessary in patient subpopulations more prone to acquiring poly-microbial SSI, such as those with neuromuscular deformities or spinal cord injury. In a retrospective observation study, Dessy et al. demonstrated that an enhanced antibiotic prophylaxis using intravenous (IV) cefuroxime for 24 hours plus vancomycin until drain removal in instrumented spinal surgery, and IV cefuroxime for 24 hours in non-instrumentation cases reduced the rate of SSIs in spine surgery [3].

There are no published data regarding the best antibiotic treatment to be used as prophylaxis in patients with neurogenic bladder. The North American Spine Society (NASS) evidence-based guidelines on antibiotic prophylaxis in spinal surgery have pointed out that potential subgroups of patients requiring effective prophylaxis against GNB may exist, although they have not been clearly defined [1]. In the case of patients with neurogenic bladder, they are more prone to urinary tract colorization and infection [4–5]. Although

asymptomatic bacteriuria (AB) should not be routinely treated in these patients because of rising resistance patterns, in the case of symptomatic urinary tract infection (UTI) antibiotic treatment should be administered and antibiotic selection should be based on local and patient-based resistance patterns so that the spectrum can be as narrow as possible [5]. In this line, recent Clinical Guidelines for the Diagnosis and Treatment of UTI of the Spanish Society of Infectious Diseases state that screening for, and treatment of, AB prior to performing instrumental spinal surgery is recommended for patients with neurogenic bladders or urinary incontinence in order to reduce the risk of gram-negative SSIs [6].

It was reported that up to 61% of children with myelomeningocele have neurogenic bladders [7–9]. Hatlen et al. demonstrated that the presence of positive urinary cultures before elective spine surgery for children with myelomeningocele leads to an increased risk of perioperative spine infections [10]. Olsen et al. conducted a case-control study to determine independent risk factors for SSI following orthopaedic spinal operations [11]. Among the patient-level factors in the univariate analysis, any incontinence (bowel or bladder, or both and preoperative or postoperative) significantly increased the risk of SSIs.

Although gram-positive organisms (particularly *Staphylococcus aureus*) predominate as causative agents for SSIs in patients undergoing spine surgery, GNB accounted for a sizeable portion of SSIs, particularly among lower lumbar and sacral spine surgical procedures [2]. Patients with incontinence, neurogenic bladder or indwelling catheters are more prone to urinary tract colonization and infection and may therefore be at higher risk of SSIs by GNB [4]. Contamination by GNB should not occur during the operative procedure, as these microorganisms are not usually present among the patient's skin flora [12]. Previous studies have suggested that GNB contamination could be secondary to hematogenous seeding originating in the urinary tract or to local skin contamination in incontinent patients, especially those undergoing surgery at the lumbosacral level [12].

Nuñez-Pereira et al. hypothesized that detecting urinary tract colonization preoperatively and adjusting antibiotic prophylaxis according to urine culture results might lower the overall SSI rate by reducing the number of GNB infections [12]. They performed a retrospective cohort study comparing two consecutive groups of patients undergoing posterior spinal fusion and instrumentation at a single institution. Cohort A included 236 patients, operated on between January 2006 and March 2007, receiving standard preoperative antibiotic prophylaxis with cefazolin (clindamycin in allergic patients). Cohort B included 223 patients operated on between January and December 2009, receiving individualized antibiotic prophylaxis and treatment based on preoperative urine culture. The study demonstrated that preoperative urine culture and individualized antibiotic prophylaxis are associated with a significant decrease in SSI due to GNB in high-risk patients undergoing spinal surgery.

Measures aimed at preventing UTI in patients with neurogenic bladder such as closed catheter drainage in patients with an indwelling catheter and the use of clean intermittent catheterization could reduce the risk of perioperative spine infections [4]. Intravesical Botox, bacterial interference and sacral neuromodulation show significant promise for the prevention of UTIs in neurogenic bladder patients [5].

1.3. PREVENTION: BONE GRAFT

Author: Dolors Rodriguez-Pardo

QUESTION 1: Does the use of allograft increase the risk of spinal infection?

RECOMMENDATION: The use of allograft seems to increase the risk for infection in pediatric and neuromuscular scoliosis, however there is no increased risk in the adult degenerative population.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 77%, Disagree 0%, Abstain: 23% (Super Majority, Strong Consensus)

RATIONALE

It has been postulated that infection risk from bone allograft may be caused by contamination or by the overwhelming of local host defenses [1,2]. Much of the data addressing this issue can be found in the pediatric literature. In a case-control study of 22 pediatric patients with infections after spine surgery, Croft et al. found that allograft use was strongly associated with surgical site infection (odds ratio (OR) = 10.7, $p < 0.0001$) [3]. Aleissa et al. showed similar results in 14 patients with SSI (risk rate (RR) 9.6, $p < 0.001$) [4]. Sponseller et al. were able to demonstrate a statistically significant increase in infection risk with the use of allograft versus autograft ($p = 0.010$) [5].

Several systematic reviews have also addressed this subject. Fei et al. performed a meta-analysis of risk factors for surgical site infection after spine surgery in 12 high-quality studies [6]. They found a relative risk for infection of 2.72% with the use of bone allograft, though there was a broad confidence interval and they failed to reach statistical significance at $p = 0.244$. Meng et al. [2] performed a systematic review of 13 studies of infection risk in pediatric spine surgery. The use of allograft carried an odds ratio of 8.498 with a high statistical significance at $p < 0.001$, though the authors cautioned about possible bias due to study heterogeneity. Glotzbecker et al. found grade C evidence of an association between allograft use and surgical site infection [7].

On the other hand, multiple studies have demonstrated that even in the pediatric literature, there is conflicting evidence. Knapp et al. studied patients with Adolescent Idiopathic Scoliosis (AIS) and found that allograft did not increase the risk for infection [8]. In a case-control study of pediatric patients undergoing spinal fusion, Shen et al. also found that there was no increased risk with allograft [9]. In the adult population, several large studies have failed to find an association between allograft use and infection. Mark et al. looked at over 1,400 patients who underwent spinal fusion, and there was no difference in infection rate when using allograft or autograft [10]. Similarly, Saeedinia et al. looked at almost 1,000 patients undergoing spinal surgery and failed to find an association between allograft and infection [11].

QUESTION 2: Can allograft, synthetic bone substitute or autograft be used during revision spinal surgery in patients with prior spine infection?

RECOMMENDATION: Based on available data, it appears that allograft, autograft and synthetic cages may be used successfully along with posterior screw fixation and prolonged antibiotic therapy in the treatment of pyogenic spondylodiscitis. This data can probably be extrapolated to also confirm that allograft and autograft safe during revision spinal surgery with prior infection.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 93%, Disagree: 7%, Abstain: 0% (Super Majority, Strong Consensus)

RATIONALE

There are several small studies suggesting that bone allograft and autograft may be used successfully with posterior screw fixation and antibiotics to treat spine infections. Dobran et al. reviewed 18 patients who underwent posterior screw fixation along with allograft and autograft for pyogenic spondylodiscitis [1]. All patients had successful fusion and normalization of C-reactive protein at a mean follow-up of 30 months. Likewise, Chung et al. reported a study of 20 patients who underwent anterior fibular allograft and posterior screw fixation for spondylodiscitis [2]. All patients had significant improvement in pain and satisfaction scores, with at least 36 months of follow-up. Only two patients had superficial wound complications. In a third study, An et al. reviewed 15 patients who underwent mixed allograft and autograft with posterior screw fusion [3]. All but one showed significant improvement in neurological deficit, functional outcome and pain, with a mean follow-up of 27 months.

Synthetic materials have also been used in the successful treatment of pyogenic spondylodiscitis. Shiban et al. reported 52 patients treated with polyetheretherketone (PEEK) cages in combination with posterior pedicle screw fixation [4]. Patients received two weeks of intravenous and three months of oral antibiotic therapy. Infection was cured in all and 16 of the 28 with some neurologic deficit improved at 12 months of follow-up. Similar results were reported with PEEK cages and posterior fixation by Schomacher et al. (51 patients, 20 months of follow-up) and Brase et al. (nine patients,

mean follow-up 13 months) [5,6]. One study compared three different types of cages (titanium mesh, titanium and PEEK) versus autologous iliac bone strut [7]. All received posterior screw fixation. There were no significant differences in clinical or radiographic outcomes, and infections were judged cured in all at a mean of 36 months for follow-up. Multiple other studies report similar findings [8–10].

1.4. PREVENTION: RISK FACTORS

Authors: Koji Yamada, Yoshihirio Uchida

QUESTION 1: Does prior or active tuberculosis (TB) preclude patients from undergoing spine surgery?

RECOMMENDATION: Prior or active TB does not preclude patients from undergoing spine surgery.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

The mainstay of treating spinal TB is chemotherapy [1]. Almost all antituberculous drugs penetrate well into tuberculous lesions [2], more than the desired minimum inhibitory concentrations (MIC) [3,4]. Abscesses usually resolve with medical therapy, as antituberculosis drugs penetrate very well [5,6].

There is controversy in the literature about the necessity of using surgical intervention in addition to spinal TB treatments. A Cochrane Database Review assessing the role of routine surgery in addition to chemotherapy in spinal TB including the studies from Medical Research Council (MRC) of the United Kingdom failed to reveal any statistically significant differences in various outcomes for additional surgery including: kyphosis angle, neurological deficit (none went on to develop this), bony fusion, absence of spinal TB, death from any cause, activity level regained, change of allocated treatment or bone loss [1]. Myelopathy with or without functional impairment most often responds to chemotherapy [7]. In two MRC studies conducted in Korea, more than 80% of patients had complete resolution of myelopathy or complete functional recovery when treated medically [8,9].

Though the review of the above trials was insufficient to say routine surgery early on was beneficial, several limitations exist [1]. First, two sets of trials reviewed in the literature were performed during the 1960s and 1970s, while in recent years new medications and better operative techniques have been developed. Second, the patients included in the MRC study were limited to two-vertebra disease with or without mild neural deficit [10,11]. The results for patients with moderate to severe motor weakness were not addressed. Moreover, the patients seen in developing countries often have a large number of vertebrae involved, accompanied with a greater chance of kyphosis progression [12] and late onset paraplegia [13,14]. Third, late onset paraplegia usually become present more than 15 years after initial spinal infection [15–17]. In MRC studies, increased progression of kyphosis was seen in the conservatively-treated group with a lower fusion rate during their follow-up period [18]. Considering the difficulties in treating severe late symptomatic post TB kyphosis, the follow-up period in these studies could be insufficient to detect the magnitude of late complications. Fourth, it is generally known that some patients do not respond well to conservative treatment and are considered nonresponders [19]. For these patients, surgery should be considered to procure adequate tissue to ascertain the diagnosis as well as to reduce the disease load.

Potential benefits of surgery include less kyphosis, immediate relief of compressed neural tissue, quicker relief of pain, a higher percentage of bony fusion, quicker bony fusion, less chance of relapse, earlier return to previous activities and less bone loss [1,2]. Early surgical intervention for prevention of deformity is relatively simple and may prevent late neurological problems due to kyphosis of the spine [15,20,21]. From a review of 124 articles, 17.1% of the procedures were performed with defined indications including: etiology, neurological deficit (severe or progressive), spinal instability with or without kyphosis (severe or progressive), multisegmental disease and paraplegia of greater than three months [19]. Surgical interven-

tion for those without neurological recovery/improvement after chemotherapy for moderate motor weakness and surgical decompression of the cord under the cover of multi-drug chemotherapy for severe motor weakness irrespective to the duration of illness or cause, are also recommended [22].

Medical treatment is generally effective for those with or without mild neural deficit. Surgical intervention may be indicated in advanced cases with marked bony involvement, abscess formation or paraplegia, regardless of prior or active tuberculosis.

Author: Carles Pigrau

QUESTION 2: Should routine methicillin-resistant *Staphylococcus aureus* (MRSA) screening be in place prior to spine surgery?

RECOMMENDATION: Routine MRSA screening should not be performed prior to spine surgery. However, in hospitals with a high incidence of *S. aureus* spinal surgical site infection (SSI) and particularly high rates of MRSA infections, MRSA screening might be useful.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 86%, Disagree: 7%, Abstain: 7% (Super Majority, Strong Consensus)

RATIONALE

According to a recent review of 161 studies, the pooled average of SSI in spine surgery was 1.9% (range: 0.1 to 22.6%) [1]. Instrumented spinal fusion had the highest rate (3.8%), followed by spinal decompression (1.8%) and spinal fusion (1.6%). *S. aureus* contributed to almost 50% of spinal SSIs with a range of 0.02 to 10%. Among *S. aureus* spinal SSIs, the pooled rate of MRSA infections was 38% [1]. The 30-day mortality rate among patients with SSI was 1.06%, double that of those without SSI (0.5%), with mortality increasing with the complexity of spinal surgery or with the presence of underlying diseases [2]. Moreover, SSIs increased re-admission rates (from 20–100%), reoperation rates (with a pooled average of 67%) and doubled health-care costs [1].

Preoperative nasal carriage of *S. aureus* has been shown to be a risk factor for SSI, but rates have been variable between studies [3,4]. Nasal decolonization with the use of topical mupirocin is utilized in 90% of cases, however, the impact of using this strategy on the reduction of SSIs in orthopaedic surgery have reported conflicting results [5,6]. A recent meta-analysis of all published studies in cardiac and orthopaedic surgery suggested that decolonization was associated with a significant decrease in *S. aureus* SSIs when either the intervention was applied to all patients or only to those who were nasal carriers [7]. Another meta-analysis showed that an absolute reduction in SSIs of 1% may be cost-effective, however, universal decolonization may increase the risk of mupirocin resistance [8].

In a not-yet published retrospective study of 1,749 patients scheduled for elective instrumented neurosurgery, the MRSA colonization rate was 0.74%. After decontamination, all MRSA carriage was eliminated and none of the 13 MRSA carriers developed an SSI, while only 1 MRSA-negative case developed a MRSA SSI.

In a recent retrospective study of 4,973 consecutive spine patients who were given cefazolin as prophylactic antibiotic therapy rather than topical nasal antibiotics for decolonization, 49 (1.1%) were MRSA carriers, and 94 (2.1%) developed an SSI, 11 of which were caused by MRSA [9]. The SSI rates were similar in nasal carriers compared to non-MRSA carriers (3 of 49 vs. 91 or 4,433, $p = 0.13$) and nasal carriage was not a risk factor for spinal SSIs.

In conclusion, in patients undergoing spinal surgery, the low level of MRSA carriage and MRSA SSI are arguments against routine MRSA screening. In hospitals with a high incidence of *S. aureus* spinal SSI and high rates of MRSA infections, MRSA screening could be useful.

QUESTION 3: Is there a role for routine decolonization of patients undergoing spine surgery? If so, what is the optimal agent(s)?

RECOMMENDATION: There is evidence to support the use of institutionalized screening and decolonization programs in methicillin-resistant *Staphylococcus aureus* (MRSA) carriers to reduce the rate of surgical site infection (SSI), however the optimum agents for decolonization have not been determined.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 91%, Disagree: 0%, Abstain: 9% (Super Majority, Strong Consensus)

RATIONALE

There is evidence to support the use of institutionalized screening and decolonization programs to reduce the rate of SSI, however the optimum agents for decolonization have not been determined [1]. Preoperative nasal MRSA colonization is associated with increased risk postoperative spinal SSI. Thakkar et al. reported screening positive MRSA SSI rates of 12% compared with screening positive for MSSA (5.73%) and screening negative (1.82%) [2]. Furthermore, Ramos et al. found increased rates of SSI in hip and knee arthroplasty and spine fusions, reporting a 4.35% SSI rate in colonized (nasal MRSA and MSSA) patients versus a 2.39% rate in noncolonized patients [3].

While widely utilized preoperatively, there is minimal evidence specifically supporting the use of chlorhexidine gluconate (CHG) showers preoperatively. The 2015 Cochrane review written by Webster et al. reported minimal evidence supporting isolated use of CHG showers preoperatively. Four reviewed trials comparing CHG to placebo found no effect, and only one trial comparing CHG showers to controls reported an improvement in SSI rate [4].

The majority of reviewed literature bundles the use of nasal decolonization with other interventions (CHG wipes, CHG showers, etc.). Multiple reviews on the effectiveness of bundled interventions for decolonization in surgical patients (including orthopaedic surgery) report reduced SSI rates with nasal decolonization and CHG wipes [5,6]. Reported studies on nasal decolonization protocols have largely shown benefit in reducing SSIs. Mullen et al. used CHG wipes and alcohol-based nasal decolonization preoperatively and reported a mean reduction rate in SSI of 81% (1.76 per 100 to 0.33 per 100) [7].

Chen et al. reviewed 19 studies of decolonization protocols on orthopaedic procedures and found significant efficacy in reducing SSIs, reporting reduction of *S. aureus* SSIs ranging from 40–200% and reduction of MRSA SSI from 29–149% [8]. Bode et al. performed a randomized, double blinded trial to determine if decolonization would reduce the SSI rate. Of 6,771 general, orthopaedic and neurologic surgery patients, 18.5% tested positive for *Staphylococcus* and were decolonized with 5 days of CHG showers and mupirocin nasal ointment. SSI rates significantly reduced from 7.7 to 3.4% using eradication compared with the placebo control [9]. These interventions are likely cost-effective as well, as Slover determined that the cost-efficacy threshold for their institution's screening and decolonization protocol would be met with a spine SSI reduction of only 10% [10].

It is our recommendation that patients who screen positive for nasal MSSA and MRSA should be decolonized using 2% mupirocin ointment applied intranasally and 2% chlorhexidine gluconate (CHG) showers for five days preoperatively. Additionally, in patients positive for MRSA, intravenous vancomycin 15 mg/kg should be administered preoperatively prior to skin incision and for 24 hours postoperatively.

QUESTION 4: How should patients currently using disease-modifying antirheumatic drugs (DMARDs) be managed in the perioperative period?

RECOMMENDATION: Spine surgeons caring for patients with rheumatic diseases must be aware that there are specific issues involved in their perioperative management. The optimal strategy for managing DMARD medications during the perioperative period of spine surgery is unknown due to the lack of evidence and it is largely based on low-quality evidence and expert opinion. A rheumatologist should be involved in the medication management around the time of surgery.

1. For nonbiologic DMARDs such as methotrexate (MTX), leflunomide, hydroxychloroquine and/or sulfasalazine, continuation of the current dose throughout the perioperative period is recommended.
2. For biologic DMARDs such as etanercept, we recommend that physicians withhold the biologic medication and plan elective surgery at the end of the dosing cycle for that specific medication. As an example, patients taking a weekly dose should schedule the surgery in the second week after the first withheld dose. These agents should not be restarted until external wound healing is complete, which is typically around two weeks. Exception: In patients taking tofacitinib (twice daily dose), withholding of tofacitinib for at least one week prior to surgery is recommended.
3. For medications typically used for systemic lupus erthematosus (SLE) patients, such as mycophenolate mofetil, azathioprine, cyclosporine and tacrolimus, the decision to withhold medications prior to surgery should be made on an individual basis.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Nonbiologic DMARDs

Although a reasonable concern exists about the potential of nonbiologic DMARDs to increase the risk of infection by affecting the immune response [1,2], stopping DMARDs prior to surgery may result in a flare-up of disease activity, which may adversely affect rehabilitation. Therefore, we suggest that patients continue the current dose of nonbiologic DMARDS throughout the perioperative period, including methotrexate (MTX), leflunomide, hydroxychloroquine and/or sulfasalazine. In clinical practice, the nonbiologic DMARD dose is often missed for one day and up to three days while the patient is hospitalized. Several studies of rheumatoid arthritis (RA) patients undergoing elective orthopaedic surgery have found that continued use of MTX through the perioperative period is safe [3,4]. A systematic review including four studies with RA patients undergoing elective orthopaedic surgery evaluated the effects of continuing MTX versus stopping MTX in the perioperative period [5]. Continued MTX therapy was safe perioperatively and was associated with a reduced risk of flares. There was no evidence to suggest that stopping MTX preoperatively reduced the incidence of infection or improved wound healing. However, in all of the studies, the mean dose of MTX was less than 15 mg per week.

The limited data on the use of leflunomide during the perioperative period is conflicting [6,7]. In one study, there were significantly more wound complications in patients taking leflunomide at the time of elective orthopaedic surgery compared with patients on MTX [7].

There are also limited data suggesting it is safe to continue hydroxychloroquine and sulfasalazine in the perioperative period. In a retrospective study of 367 orthopaedic surgeries among 204 RA patients, two-thirds of whom were receiving nonbiologic DMARDs including hydroxychloroquine and sulfasalazine, there was no increased infection associated with nonbiologic DMARD use [8].

Biologic DMARDs

We recommend that surgeons withhold biologic medication and plan the elective surgery at the end of the dosing cycle for that specific medication. As an example, patients taking weekly etanercept should aim to schedule the surgery in the second week after the first withheld dose. Patients taking adalimumab in two-week intervals should plan the surgery in the third week after the first withheld dose. In a similar manner, patients on monthly intravenous abatacept should schedule the surgery in the fifth week after the first withheld dose. Patients taking rituximab should wait until month seven after the last dose to schedule the surgery, presumably when B cells have returned to the circulation. However, nonelective procedures should not be delayed in patients who have been recently treated.

There is relatively little evidence available regarding the optimal timing for use of biologic DMARDs in the perioperative period, and our recommendation is largely based on indirect evidence suggesting an increased risk of infection associated with their use [9–11]. Many [12–16], but not all [17,18] retrospective studies suggest that use of tumor necrosis factor (TNF) inhibitors do not increase the risk of postoperative infections or impair wound healing.

The infectious risks of abatacept are similar to those of TNF inhibitors and other biologic agents, but there are no trials that have examined abatacept's safety perioperatively [9,19]. A case series described eight uncomplicated surgeries in seven RA patients on abatacept [20]. Similarly, there is no direct evidence regarding the safety of the interleukin (IL)-1 receptor inhibitor anakinra in the perioperative period. Conclusions regarding perioperative safety are largely based on trials in nonoperative patients showing that the infection rate was similar to that in patients receiving placebo [21].

These agents should not be restarted until external wound healing is complete, which is typically around two weeks. There is no evidence regarding the optimal time to restart biologic DMARDs in the perioperative setting and this approach is based on standard precautions used for biologic agents that warn against use in patients with active infection, such as an open wound.

Antirheumatic Kinase Inhibitor

In patients taking tofacitinib, we (Fang et al.) withhold the medication for at least one week prior to surgery. Tofacitinib is an orally-administered Janus kinase (JAK) inhibitor that is used in the management of patients with moderately to severely active RA. Our recommendation is based on indirect evidence from systematic reviews and meta-analyses of tofacitinib in nonsurgical patients showing there is an increased risk of infection with tofacitinib compared with placebo. Although the half-life is thought to be short for tofacitinib, there is uncertainty regarding the duration of immunosuppression after the drug is held [22].

Other SLE-specific Medications

There is uncertainty regarding the optimal perioperative medication management in patients with SLE given the lack of data. More data are needed to help guide perioperative medication management in lupus patients, including information on hydroxychloroquine, MTX, mycophenolate mofetil, azathioprine, cyclosporine and tacrolimus. Given the clinical spectrum of SLE disease severity and organ involvement, the decision to withhold medications prior to surgery should be made on an individual basis. Thus, for patients with severe SLE and multi-organ involvement in which discontinuation of the medication may result in a disease flare, it is reasonable to continue the medications through the surgical period. This is based on indirect evidence from organ transplant patients that supports continuing anti-rejection therapy during the time of surgery [23,24].

QUESTION 5: Is postoperative hyperglycemia a risk factor for the development of infection following spinal surgery?

RECOMMENDATION: From the limited evidence, the association between postoperative hyperglycemia and surgical site infection (SSI) remains unclear and further study is needed.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 93%, Disagree: 7%, Abstain: 0% (Super Majority, Strong Consensus)

RATIONALE

Postoperative hyperglycemia does not only occur in patients diagnosed with diabetes mellitus (DM). Only 41% of patients with serum glucose levels greater than 200 mg/dL were identified in the medical records with the diagnosis of diabetes [1]. Langlois et al. suggested that non-diabetic patients experienced a statistical increase in blood glucose levels in the first three days following spine surgery [2]. They also pointed out the possibility of blood glucose elevation in non-diabetic patients associated with postsurgical complications. After major surgery, perioperative blood glucose elevations may be associated with previously undiagnosed DM, or occur because of the activation of the hypothalamic-pituitary axis, a physical response to severe stress in individuals at risk [3].

DM is a disease of uncontrolled hyperglycemia, which impairs the immune system. The wound healing in patients with diabetes is impaired as a result of microangiopathic changes and ischemia, impaired granulocyte function and a lack of platelet-derived growth factor function in the wound [4]. Despite the lack of multiple randomized clinical trials, various retrospective studies have found that DM is strongly associated with SSI after spinal surgery [5–16]. Moreover, DM increases the risk of not only SSI but other postoperative complications such as urinary tract infection, unplanned readmission and prolonged length of stay [17–19].

From a retrospective case-control study of patients who underwent an orthopaedic spinal operation performed at a university-affiliated tertiary care hospital, the risk of SSI, the odds ratio for postoperative hyperglycemia (> 200 mg/dL), was 2.9 (95% confidence interval (CI): 1.2, 6.5) after univariate analyses. But, the risk did not remain significant after multivariate logistic regression analysis [11]. A retrospective case-control study evaluating 104 patients with SSI after spinal surgery matched with 104 randomly-selected control patients without SSI after spinal surgery, revealed that patients with postoperative glucose measurements greater than 126 mg/dL within 48 hours after surgery were significantly more likely to develop an SSI than patients without an elevated glucose measurement on univariate analysis (crude odds ratio: 3.2, 95% CI: 1.6, 6.3). But, it was not significant after adjusting for other variables [20]. A retrospective case-control study evaluating specific independent risk factors for SSI after laminectomy or spinal fusion at a tertiary care hospital affiliated with a university hospital, identified that high serum glucose (> 200 mg/dL) at any time during hospitalization was significantly associated with SSI in the univariate analysis (odds ratio: 3.0, 95% CI: 1.4, 6.3) [1].

On the other hand, a retrospective study evaluating perioperative variables to determine the risk factors for SSI in a total of 2,715 patients undergoing posterior lumbar spinal surgery revealed that high preoperative serum glucose (odds ratio: 1.169, 95% CI: 1.016, 1.345) and a history of DM (odds ratio: 2.227, 95% CI: 1.100, 4.506) were associated with SSI in multivariate logistic regression analysis, although postoperative serum glucose level showed no association [21]. In another retrospective study using the Nationwide Inpatient Sample (NIS) database, uncontrolled DM revealed a higher risk of postoperative infection (odds ratio: 4.90, 95% CI = 2.84, 8.46) than controlled DM (odds ratio: 1.91, 95% CI: 1.54, 2.37) [7]. But, there was no ICD-9-CM coding standard or parameter in the clinical setting that provides standardization of "uncontrolled" or "controlled" diabetic patients. Furthermore, the NIS does not provide quantitative data on blood glucose levels or hemoglobin A1c (HbA1c) percentage, making it impossible to further stratify cohorts based on overall control of a patient's diabetic condition.

Limited evidence supports the association between perioperative HbA1c and SSI [22,23]. The cut-off values for HbA1c differ among studies and the results were originated from small retrospective studies without multivariate analyses. Larger prospective studies are needed to confirm the association.

Though DM is strongly related to SSI in spinal surgery, no observational studies were able to reveal a significant association between postoperative hyperglycemia and SSI in multivariate analyses. From the limited evidence, the association between postoperative hyperglycemia and SSI remains unclear, and further study is needed on this issue.

QUESTION 6: Is there an association between urinary tract infection (UTI) and surgical site infection (SSI) following spinal surgery?

RECOMMENDATION: Evidence regarding an association between UTI and SSI following spine surgery is conflicting and no convincing relationship has been proven. In a like fashion, no convincing relationship has been established between asymptomatic bacteriuria and SSI following spine surgery.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 71%, Disagree: 21%, Abstain: 8% (Super Majority, Strong Consensus)

RATIONALE

The treatment of organisms isolated from urine culture in the setting of orthopaedic surgery with hardware implantation is controversial and has been often driven by anecdote. The risk of seeding of hip and knee arthroplasties from asymptomatic bacteriuria has been studied and found to be small, with no cases in two studies [1,2]. A systematic review of the topic concluded that there was no evidence to support a direct causal relationship between perioperative asymptomatic bacteriuria and arthroplasty infection [3].

Data from the American College of Surgeons National Surgical Quality Improvement Program suggests that UTIs occur in nearly 1 of 50 patients undergoing posterior lumbar fusion procedures [4]. However, there are few studies that directly address a relationship between UTI and SSI in instrumented spine surgery. Nunez-Pereira et al. studied 466 patients, of whom 89 had UTIs and 54 had SSIs, with 22 patients having both [5]. Of these 22, the same organism was isolated from the surgical site and urine in nine patients. UTI conferred an odds ratio (OR) of 3.1 for SSI, though the statistical analysis recognized all UTIs and not just infections with the same organism. Tominaga et al. studied a cohort of 825 patients with 14 patients who developed SSIs and 20 patients who developed UTIs, and found no association between SSI and UTI [6].

It seems germane as well to address the relationship of asymptomatic bacteriuria and postoperative spine infection. Lee et al. studied 355 women > 65 years of age undergoing spine surgery [7]. Of these, 42 developed asymptomatic bacteriuria, with no association with SSI. A statistically significant association was found between asymptomatic bacteriuria with a Foley catheter in place and infection in patients who had undergone instrumentation of multiple levels. However, of 15 patients with postoperative infections, only 2 had the same organism (*Staphylococcus epidermidis* in both cases) isolated from cultures of surgical site and urine.

QUESTION 7: What are the risk factors predisposing a patient to surgical site infections (SSI) after spine surgery?

RECOMMENDATION: Numerous risk factors for SSIs following spine surgery have been identified, including diabetes, obesity, prior SSI, smoking, longer operative times, posterior approach to spine and the number of levels fused.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

The relatively low incidence of postoperative SSIs after spine surgery makes it challenging for studies to evaluate the risk factors for SSI in a prospective manner [1]. Based on our literature search, a number of retrospective studies and a single prospective study were identified. The findings of prior studies have also been summarized by multiple systematic reviews. Pull ter Gunne et al. performed a systematic review of 24 studies that identified risk factors for SSI after spine surgery [2]. All 24 studies were case-control and case series. There was a total of 73 potential factors evaluated, 34 of which were found to be significant in at least 1 study. There were 11 risk factors that were found to be significant in at least 2 studies. Among all risk factors, diabetes, obesity and prior SSI were the only three that were confirmed as risk factors by a multitude of studies.

Similarly, there was another systematic review which analyzed 36 observational studies for which 46 independent factors were studied [3]. Only six risk factors had been consistently proven to show an association with SSI after spine surgery, including diabetes, obesity, longer operative time, smoking, history of SSI and type of surgical procedure (i.e. tumor resection).

More recently, a prospective multicenter surveillance study was performed which enrolled 2,736 patients who underwent posterior thoracic and/or lumbar spine surgery [4]. Of these patients, 24 (0.9%) developed postoperative deep SSI. Preoperative steroid therapy, spinal trauma, male gender and prolonged operating time (> three hours) were found to be independent risk factors for SSI after spine surgery. Several previous retrospective studies have not identified preoperative steroid use and male gender as risk factors for SSI after spine surgery [2,5,6].

An ongoing prospective study funded by Pfizer evaluating the potential role of vaccination against *Staphylococcus* is likely to provide valuable information regarding the most important risk factors for SSI after spine surgery.

QUESTION 8: Should all patients with psoas abscesses be screened for both spine and hip infections?

RECOMMENDATION: Cross-sectional imaging with computed tomography (CT) and magnetic resonance imaging (MRI) will identify the source of secondary psoas abscesses in the majority of cases. If no other source is identified, consider cross-sectional imaging with CT or MRI for both the hip and spine in the setting of psoas abscess.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain 0% (Unanimous, Strongest Consensus)

RATIONALE

The iliopsoas is formed by two distinct and separate muscles - the psoas major and iliacus muscles. Each muscle is covered by its respective fascia and is typically associated with different disease entities [1]. The psoas major arises from the transverse processes of the lumbar vertebrae, exiting the pelvis beneath the inguinal ligament where it joins the iliacus (forming the iliopsoas tendon) and inserts on the lesser trochanter of the femur [2]. The iliacus muscle originates from the superior portion of the iliac fossa, superior lateral aspect of the sacrum and ventral sacroiliac and iliolumbar ligaments [2]. The medial portion of the iliacus muscle joins the psoas major tendon (forming the iliopsoas tendon) and inserts on the lesser trochanter. The lateral portion of the muscle inserts

directly on the anterior and anteromedial aspect of the femur below the lesser trochanter [3].

The literature often does not delineate between the two muscles, referring to the combined muscles as the iliopsoas or simply the psoas muscle. Making a distinction between these muscles can help determine the source of infection. With regards to musculoskeletal infections, the majority of psoas muscle abscesses reflect extension from an adjacent spondylodiskitis or septic facet [4–7]. In contrast, iliacus muscle abscesses are secondary to extension of an underlying hip infection through the iliopsoas bursa or infectious sacroiliitis.

The iliopsoas bursa is the largest bursa in the body and communicates with the hip joint in 14% of the population [8]. Communication of the joint capsule with the iliopsoas bursa is likely increased following hip arthroplasty [9]. With the majority of the bursa located deep in the iliacus muscle, hip joint infections typically involve the iliacus muscle alone or less often both the iliacus and psoas muscle [1,10]. When the psoas muscle is involved, there should be visible communication with a distended iliopsoas bursa. This is in contrast to the psoas abscess associated with spondylodiscitis, which does not involve the bursa.

Both lumbar spine osteodiscitis and septic hip arthritis can be associated with psoas abscess [11]. The spine as primary source of infection for secondary psoas abscess should always be included in the differential diagnosis [12]. Studies have reported that 10–36% of secondary psoas abscess is caused by disc infection [13,14]. The anatomical proximity and communication of the psoas muscle to the hip joint capsule creates a potential transit for bacterial spread from spine to the hip joint or vice versa [15]. Screening patients with a psoas abscess for both hip and spine infection can prevent this harmful infectious spread. However, it should also be considered that the infection may simultaneously result in multiple infection sites from the same original hematogenous source of psoas abscess or spinal infection.

A non-coincidental association exists between psoas abscess and hip infection, both in the virgin hip joint and in a prosthetic hip joint. There have been multiple reports regarding the progression of the extension of psoas abscesses into the virgin or prosthetic hip joints [16–19]. In one study, the percentage of prosthetic hip infections with associated psoas abscesses has been reported to be as high as 12% [19]. Hematogenous prosthetic infection and a medical history of neoplasm have been reported as risk factors of psoas abscess in patients with an infected hip replacement [19]. Psoas abscesses may also cause relapse of prosthetic hip infection.

It is recommended that practitioners screen patients with psoas abscesses for hip infection and spinal infection due to their anatomical communication, relationship in etiology and co-prevalence. Clinicians should be aware of the potential communication between the lumbar spine and hip joint via the psoas muscle and iliopsoas bursa. Successful treatment outcomes of psoas abscess are not only related to its early diagnosis, but also to the prompt detection of its spread to adjacent organs with potentially devastating outcomes, including the neural elements of spine and a prosthetic hip joint.

1.5. PREVENTION: WOUND CARE

Author: Carles Pigrau

QUESTION 1: Is negative pressure wound therapy (NPWT) safe on spinal wounds in patients with a cerebrospinal fluid (CSF) leak?

RECOMMENDATION: NPWT may be harmful in patients with a CSF leak, leading to severe neurological sequelae.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 93%, Disagree: 7%, Abstain: 0% (Super Majority, Strong Consensus)

RATIONALE

Intracranial hypotension may develop after dural puncture or spinal surgery by accidental intraoperative opening of the dura. As a complication to this, several cases of accidental drainage after spinal surgery and application of negative pressure suction devices (NPSDs) have been reported [1–4]. Secondarily, intracranial hypotension may develop leading to tonsillar herniation, subdural hemorrhage, severe neurological sequel and even death.

Recently, Sporns et al. reviewed the literature published in reference to patients diagnosed with postsurgical or post-traumatic intracranial hypotension [1,4]. In 24 relevant reports that included 27 cases, in 15 cases a NPSD (including NPWT or pleural drainage after thoracic surgery or traumatism) was applied, ten had no negative pressure devices and two could not be determined for application of a suction drain. All patients with NPSD had severe neurological symptoms, while only mild symptoms were observed in cases without such devices. They concluded that the increasing use of NPSDs causes the reported condition and that acute intracranial hypotension should be considered as an explanation of postoperative neurological symptoms or coma after cranial or spinal surgery. A precise radiological examination (preferably with magnetic resonance imaging) can help to rule out intracranial hypotension and dural laceration.

In conclusion, in patients with spinal wounds, NPSDs (including pleural drainages) may be harmful and lead to more severe neurological sequel than those cases with liquoral hypotension secondary to dural laceration without negative pressure devices.

Author: Barrett Boody

QUESTION 2: What are the risks and benefits for the use of vacuum-assisted closure (VAC) devices/PICO dressings following spine surgery?

RECOMMENDATION: The use of incisional VAC therapy (such as PICO dressings) is limited, but available literature supports its use in the prevention of dehiscence and surgical site infection (SSI) in posterior thoracolumbar deformity surgery.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 86%, Disagree: 14%, Abstain: 0% (Super Majority, Strong Consensus)

RATIONALE

Multiple case series and case reports have been published supporting the use of VAC therapy for staged treatment of deep/subfascial SSI in spine surgery, with the common use being at index or second debridement, followed by multiple VAC changes until the wound is suitable for closure [1–4]. The specific VAC techniques (such as fascia open or closed, number of suction devices, suction settings, etc.) is poorly described in available studies. Ploumis reported on 73 patients undergoing VAC therapy for deep SSI, noting an average of 1.4 procedures following VAC placement (including closure) and closure of wound at an average of 7 days. They noted that methicillin-resistant *Staphylococcus aureus* (MRSA) and polymicrobial wound infections were more likely to require subsequent debridement after index VAC placement prior to definitive closure [2]. Similarly, Mehbod described 20 similar patients with deep SSI following spine surgery treated with VAC therapy, with an average of 2.2 procedures (including closure) following index VAC placement and resolution of infection in all patients and closed wounds by 6 months [3]. Canavese described 33 pediatric patients treated with VAC therapy for deep SSI after thoracolumbar spine surgery, with only 1 case ultimately requiring partial removal of implants [5].

Complications for VAC therapy have also been widely described, including need for reoperation and/or revision of hardware, bleeding, flap closure or skin grafting, retention of foam sponge fragments and cerebrospinal fluid (CSF) leaks resulting in neurologic complications (coma, brain herniation and intracranial hemorrhage) [1,2, 6–8]. The use of VAC therapy in the setting of CSF leak should be avoided due to risks of tonsillar herniation [7]. While VAC therapy over dura has been described in cranial surgery, no publication specifically described the application of sponges over dura in spine surgery. Multiple cranial publications describe the technique for dural application as the use of the "white" sponge (polyvinyl foam), as it is hydrophilic and less adherent, with lower suction pressures (~ 50 mmHg) [9,10].

The only available paper on the application of incision VAC therapy (such as PICO dressings) for spine surgery was published by Adogwa et al., who reviewed 160 posterior thoracolumbar deformity surgeries, of which 46 used incisional negative pressure wound therapy for 3 days. The authors reported lower rates of wound dehiscence (6.38% vs. 12.28%) and lower SSI rates (10.63% vs. 14.91%) for the incisional negative pressure wound therapy group, both reaching statistical significance ($p < 0.05$) [11].

Author: Jeffrey A. Rihn

QUESTION 3: What type of surgical dressing is most effective for lowering rates of surgical site infection (SSI) in patients undergoing spine surgery?

RECOMMENDATION: There are no randomized studies comparing the use of incisional negative pressure wound therapy (NPWT) to standard dry dressings in spine surgery. The World Health Organization (WHO) recommends the use of incisional NPWT for high risk surgical wounds to reduce the risk of SSI.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 86%, Disagree: 0%, Abstain: 14% (Super Majority, Strong Consensus)

RATIONALE

Incisional NPWT in the form of commercially available incisional suction dressings has recently gained popularity in the management of high-risk wounds in orthopaedic surgery.

These dressings are used at the time of index surgery primarily, with the aim of preventing wound complications such as SSI. Incisional NPWT protects the healing wound by preventing wound edge motion, improving of blood supply, removing of excess fluid and stimulating granulation tissue. A recent meta-analysis of all randomized and case-controlled trials comparing incisional NPWT to standard of care showed a reduction in SSI (50%), wound dehiscence and hospital length of stay [1]. In a pig spine model, Glaser showed improved early biomechanical properties as well as cosmesis in wounds dressed with incisional NPWT compared to standard dry dressings [2].

There are only two studies that have investigated incisional NPWT after spine surgery. A single-institution retrospective case-control study from Duke University showed a 50% decrease in wound dehiscence and a 30% decrease in SSI after a change to incisional NPWT dressing for thoracolumbar deformity wounds [3]. Similarly, a small randomized trial by Nordmeyer et al. showed a decrease in seroma and the need for nursing wound care intervention in patients who were treated with incisional NPWT [4]. The authors hypothesized that a decrease in seroma may lead to decreased SSI, but the study was underpowered to show this difference.

The 2016 WHO recommendations on intraoperative and postoperative measures for SSI prevention proposed prophylactic NPWT on primarily closed surgical incisions in high-risk wounds to reduce the incidence of SSI [5]. This recommendation drew on evidence from abdominal, thoracic and orthopaedic surgery.

In the absence of high-quality randomized trials and given the WHO recommendation, it would be reasonable to use incisional NPWT in settings where the surgeon believes the wound is at risk of infection or breakdown. Spine wounds at high risk of infection include those in patients with diabetes, increased BMI, extended operative times and chronic steroid use [6,7]. In the pediatric spine population, risk factors for SSI include high weight centile, neuromuscular scoliosis, greater comorbidities and prolonged operative time [8].

Diagnosis

2.1. DIAGNOSIS: GENERAL PRINCIPLES

Authors: Robert Sawyer, Joseph K. Weistroffer, Anna White

QUESTION 1: What is the definition of surgical site infection (SSI) in spinal surgery?

RECOMMENDATION: We recommend utilizing the definition provided by the Centers for Disease Control and Prevention (CDC), National Healthcare Safety Network (NHSN) Patient Safety Component Manual, Chapter 9: Surgical Site Infection (SSI) Event.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

The most persuasive argument for adopting the CDC's definition for an SSI lies in utilizing search protocols to map International Classification of Disease, 10th revision, Procedure Classification System (ICD-10-PCS) and Current Procedural Terminology (CPT) codes when querying databases.

The CDC definition is the accumulation of multiple years of planning/tracking and modifying this instrument via annual reviews and input from professionals worldwide. The description includes such categorical sub-elements as the definition of an operative procedure and the definition of an operating room. It includes criteria for the sub-classifications of a superficial incisional SSI, deep incisional SSI and organ/space SSI [1]. The CDC's definition delineates the exclusion of such events as cellulitis, stitch abscesses, as well as stab wound or pin site infections. It also defines such infections about primary or secondary wounds and the surveillance periods for SSI following operative procedures. Furthermore, numerous spine-related studies have utilized the same definition put forth by the CDC [2–5].

Adopting a thorough and uniform definition for SSI is imperative, as studies have shown that the rate of SSI following spine surgery varies based on the definition used [6]. In addition, having a standardized definition will improve surveillance, provide consistency among studies and improve overall patient care.

Author: Claus Simpfendorfer

QUESTION 2: What defines delay in the diagnosis of a spine infection?

RECOMMENDATION: There is no clear or established definition of delayed diagnosis for spine infection.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

The diagnosis of spinal infections is often delayed from one to three months from the onset of symptoms [1,2]. Delay in diagnosis is frequently secondary to nonspecific symptoms including back and neck pain. A couple of studies have used delayed diagnosis

of greater than eight weeks as a predictor of lower recovery rates, neurologic deficits and long-term disability [2–4]. A recent study by Issa et al. demonstrated that the percent of positive cultures from blood and/or biopsy decreases as the delay in diagnosis increases [2–5].

Jean et al. looked at predictors of delayed diagnosis and found that X-rays resulted in an increased delay from 14 days to 34.7 days [6]. It is presumed that, although delaying diagnosis, X-ray findings (either normal or demonstrating degenerative changes) provide the physician with reassurance. Alternatively, Jean et al. found that fever at initial presentation, elevated C-reactive protein (CRP) and blood cultures shortened the time to diagnosis [6]. The most significant impact was the elevated CRP which shortened the diagnostic delay from 73 days to 17 days [6]. It is therefore suggested that CRP be routinely checked in cases of new onset or sudden increased back pain [6,7]. Furthermore, if CRP is elevated or if there is clinical suspicion for spine infection, MRI with gadolinium should be performed [8].

QUESTION 3: Is there an optimal window for diagnosis of an early spine infection?

RECOMMENDATION: There is no defined window, but early diagnosis of a postoperative spine infection (up to three months from time of surgery) treated with surgical debridement and antibiotics often allows for retention of instrumentation.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 93%, Disagree: 7%, Abstain: 0% (Super Majority, Strong Consensus)

RATIONALE

Although the evidence regarding this topic is from low-quality studies, the findings and recommendations are consistent. Most postoperative spinal infections in adults present early, typically within the first three months [1]. Early diagnosis and debridement typically allows for retention of implants when present [1]. Implant removal due to infection can result in satisfactory results and eradicate infection, but can lead to malalignment and pseudarthrosis [2].

Early spine infections (< three months after surgery) treated with irrigation and debridement have improved outcomes compared to before surgery, but cause increased back pain and a lower probability of achieving a minimal clinically important difference [3].

In a cohort study of 51 patients who developed a postoperative spinal implant infection, prompt treatment (< 3 months) with debridement allowed for implant preservation in 41 patients, versus 10 patients in which treatment was delayed and implants were removed [4]. Another case series identified 26 postoperative infections, of which 24 were able to be treated without removal of implants by aggressive debridement and secondary closure [5]. Early identification and treatment can often allow for implant retention compared to delayed presentation, when implants may need to be removed [6–8].

Late spine infections are, however, seen more commonly in idiopathic scoliosis cases [9]. In a case-controlled series of 236 patients, seven developed an infection [10]. One was early and the other six were diagnosed at an average of 34.2 months postoperatively.

It is typical for patients to have symptoms of low back pain for 4 to 10 weeks prior to diagnosis of spondylodiscitis [11,12]. Although most studies recommend early treatment, no specific timeframe could be identified that definitely leads to better outcomes.

Author: Gregory Schroeder

QUESTION 4: How do early and late infectious complications differ following spine surgery?

RECOMMENDATION: Early infections, defined as occurring within 30 days of surgery, often present with local signs of infection such as increased surgical site pain, erythema, warmth and wound drainage. Conversely, late infections (> 90 days after surgery) commonly present with an insidious onset of chronic pain and implant failure/ pseudarthrosis if following a fusion.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 87%, Disagree: 0%, Abstain: 13% (Super Majority, Strong Consensus)

RATIONALE

Postoperative spine infection occurs at a rate of 0.7–16% depending on the procedure; the lumbar spine is the site of 51% of infections [1].

A postoperative infection is classified as early when it occurs within 30 days of the initial surgery. Early infections typically present with increasing back pain (83–100%) as the primary symptom [2,3]. Fever, weight loss, erythema, swelling, warmth, tenderness and elevated white blood cell (WBC) count may also be present, with fever having an incidence of 16–65% [2–4]. One of the most reliable and specific signs of early infection is increased wound drainage (67%) as it can occur in both deep and superficial infections [4].

A postoperative infection occurring three to nine months following surgery can be classified as a late infection. As opposed to early infections, late infections typically present with delayed symptoms such as lack of adequate fusion, chronic pain or implant failure months after surgery [5]. Local symptoms may also occur, including increased pain and tenderness at the incision site. Wound drainage may occur but is less common than in early infections [5].

Complications of postoperative spine infection include impairment of function, significant morbidity and increased health care costs approximating up to $200,000 per patient [1,3]. Increase in hospital stay and increased rates of repeat surgery have also been observed.

Gram-positive bacteria, specifically *Staphylococcus aureus,* are responsible for approximately 45% of spine infections [6]. Other gram-positives such as *Staphylococcus epidermis* and *Enterococcus* as well as gram-negatives *Pseudomonas aeruginosa* and *Escheria coli* have been observed at lower incidences [1,2,6]. There is no clear association between type of surgical procedure and bacteria strain. However, gram-negatives tend to present more commonly in sacral and lumbar regions [6]. Fungal infections may occur in immunocompromised patients. *C. acnes* has recently been identified as another potential causative organism [2]. No significant difference has been observed in the type of organism present in early and late infections.

QUESTION 5: Are there patients with degenerative pathology, such as disc herniations, who are actually infected with a low-grade infection (e.g., *Propionibacterium acnes*)?

RECOMMENDATION: The association between the *Cutibacterium acnes (C. acnes)* (formerly *P. acnes*) and degenerative spinal disease is inconclusive.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 86%, Disagree: 14%, Abstain: 0% (Super Majority, Strong Consensus)

RATIONALE

The initial connection between potential low-level infection and degenerative spinal pathology was drawn when a group identified over half of discectomies performed for disc herniation as culture positive for *C. acnes* or coagulase-negative *Staphylococcus spp* [1]. A large number of predominantly small studies have since come to opposite conclusions on the connection between these bacteria and degenerative spinal disease, most commonly evaluated radiographically by the presence of Modic changes (examples of those finding no relationship [2–7] versus those finding a correlation [8–12]). One controversial placebo-controlled, double-blinded trial administered extended-duration antibiotic therapy to those patients with Modic type 1 changes and demonstrated better pain resolution in those receiving antibiotics [8].

Recent systematic reviews, each published in 2015, independently concluded that while there was strong evidence from multiple studies that patients undergoing spinal surgery have increased rates of bacteria at the site of degenerative disease of spine, causation between that finding and the pathologic changes resulting in back pain were unclear [1,13,14].

One important cause for heterogeneity in the data is the possibility that microbiologic sampling could be more readily contaminated with bacteria based on differences in surgical and collection technique [3,15]. However, this does not fully explain the fact that in clinical studies, *C. acnes* is consistently the most common, if not only, organism isolated. Recent studies, including control groups of patients not anticipated to have infectious etiologies for their spinal condition, have also noted increased rates of bacterial presence in degenerative disease compared to patients without degenerative disease [2,16]. Methods attempting to disrupt biofilm-encapsulated bacteria have attempted to explain negative culture results from earlier studies [10,17]. Similarly, molecular subtyping of *C. acnes* allows for better characterization of these isolates into those more likely to be routine skin contamination from those more likely to be pathogenic [2,17–19]. These studies have demonstrated a mixture of these subtypes present, with those generally not representing skin flora predominating. Recent studies have additionally investigated histologic methods [20], inflammatory cytokine responses [16,21] and proteomic analysis [22] in addition to bacterial presence as a marker for true infection. Finally, some groups have recently used animal models to attempt to support a connection between bacterial inoculation and symptomatic spinal pathology [23,24].

Though still unverified, there is an enlarging body of evidence using modern techniques and accounting for technical limitations in earlier studies for the role of infection in at least some types of degenerative spinal pathology. A well-designed, multicenter trial effort, which successfully confirms this connection would allow for reasonable consideration of further studies utilizing antibiotic therapy as a non-invasive therapy option for degenerative disc disease.

QUESTION 6: What is the diagnostic algorithm of patients with suspected hematogenous vertebral osteomyelitis? Is the algorithm different for patients with tuberculosis (TB)?

RECOMMENDATION: We support the diagnostic algorithm for suspected hematogenous vertebral osteomyelitis per Infectious Disease Society of America (IDSA) Clinical Practice Guidelines, 2015. Diagnostic algorithm is not different for patients with TB.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 87%, Disagree: 6%, Abstain: 7% (Super Majority, Strong Consensus)

RATIONALE

Vertebral osteomyelitis typically occurs due to hematogenous seeding of the adjacent avascular disc from a distant foci [1]. Appropriate management is contingent upon timely diagnosis. Patients with vertebral osteomyelitis are commonly misdiagnosed and treated for degenerative pathology [2]. This often leads to a delay in treatment on average from two to four months [3]. The diagnosis of vertebral osteomyelitis is not challenging in patients with acute onset low back pain and fever. In this circumstance the diagnosis can be confirmed with a serologic test and imaging studies. However, fever and leukocytosis occur in approximately 45% of patients with bacterial vertebral osteomyelitis and very rarely in those with fungal, brucellar or mycobacterial infections [4,5]. Vertebral osteomyelitis should be suspected in patients who have recalcitrant back pain in the setting of elevated inflammatory markers. In 2015, the IDSA published Clinical Guidelines for the diagnosis and treatment of native vertebral osteomyelitis (NVO) in adults [6,7]. These guidelines provide an algorithmic approach to the diagnosis of NVO based on a systematic review of the literature.

Obtaining a detailed history is a critical portion of the diagnostic algorithm and should include any recent travel, infections, open wounds, recent antibiotic treatment and intravenous drug use. Patients who have back pain and a history of bacteremia, particularly *Staphylococcus aureus,* should be suspected of having vertebral osteomyelitis; therefore, further work up is warranted in these scenarios [8–10]. Patients with vertebral osteomyelitis typically present with back pain exacerbated by physical activity. Pain may not be isolated to the affected area and can radiate to the abdomen, hip, leg, scrotum, groin or perineum [11]. A full physical examination should be performed and include assessment of motor and sensory function. It takes three to six weeks after the onset of symptoms for bone destruction to be evident on plain radiographs. Thus, normal images do not exclude diagnosis.

Magnetic resonance imaging (MRI) should be obtained in patients with suspected vertebral osteomyelitis, as it has a sensitivity of 97%, specificity of 93% and an accuracy of 94% in diagnosing vertebral osteomyelitis [12,13]. Gadolinium enhancement is critical to appreciate paravertebral or epidural involvement [14]. A repeat MRI should be considered in two to four weeks in a patient suspected of vertebral osteomyelitis whose initial imaging study failed to show features consist with the diagnosis [15]. Imaging features consistent with TB infections include destruction of two or more contiguous vertebrae, extension along the anterior longitudinal ligament and disc infection, with or without a paraspinal mass or mixed soft tissue fluid collection [16]. In patients for whom MRI is not possible, a spine gallium/Tc99 bone scan is an alternative with a sensitivity and specificity of around 90% for diagnosing vertebral osteomyelitis [17,18]. Positron emission tomographic scanning is also highly sensitive for detecting osteomyelitis [19].

Serologic testing is important in the diagnostic algorithm of vertebral osteomyelitis. A minimum of two blood cultures should be obtained for patients with suspected vertebral osteomyelitis [20]. Blood cultures should be incubated for up to two weeks and should include aerobic, anaerobic and fungal. Leukocytosis has low sensitivity and specificity in the diagnosis with approximately 40% of patients with osteomyelitis having a normal white blood cell (WBC) count [21]. However, an elevated erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) in patients with back pain, though not specific, has a sensitivity that can range from 94% to 100% [22].

In patients with suspected vertebral osteomyelitis who reside in or have traveled to areas endemic for TB, a purified protein derivative (PPD) skin test can be performed; however, this test has a low sensitivity and specificity for diagnosis. An interferon-γ release assay has been shown to have a higher sensitivity than PPD, especially in immunocompromised patients with immune compromise [23]. Enzyme-linked immunospot assay has some diagnostic utility for TB and has been proven superior to PPD alone (sensitivity 82.8% vs. 58.6% and specificity, 81.3% vs. 59.4%, respectively) [24].

Empiric antibiotic therapy should not be initiated in aseptic patients without neurologic deficit until an image-guided biopsy can be obtained, especially if microbiologic diagnosis for a known associated organism has not been established by blood cultures or serologic tests [6]. Biopsy increases the likelihood of microbiologic diagnosis, improving the chance of successful medical management through targeted antibiotic therapy [25]. *S. aureus* bacteremia eliminates the need for biopsy, and antibiotics should not be delayed [8,22]. If biopsy is non-diagnostic, a repeat biopsy, image-guided or open biopsy, should be considered.

QUESTION 7: Should antibiotics be held prior to image-guided biopsy/aspiration for a suspected spine infection?

RECOMMENDATION: We recommend that prior to image-guided biopsy/aspiration for a suspected spine infection, all antibiotics should be withheld until after appropriate culture samples are obtained. Antibiotic administration, without aspiration/biopsy may be justified in patients who are critically ill and cannot withstand intervention or in patients with deteriorating neurological conditions.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 93%, Disagree: 0%, Abstain: 7% (Super Majority, Strong Consensus)

RATIONALE

The definitive diagnosis of spinal osteomyelitis can be made only with isolation of the organism from a positive blood culture or biopsy and culture of the tissues from the region of the infection. Spinal biopsies may be performed using computed tomography (CT) or fluoroscopy for guidance in localizing the site of the suspected infection. The identification of the infecting organism is useful in directing antibiotic therapy. In suspected infection of the spine, biopsy and culture of the tissues from the affected site has been reported to be successful in the identification of the infecting organism in 46–91% of cases [1–5].

In real practice, there are some instances where antibiotic treatment is empirically instituted before the patient has been biopsied. Such cases may include patients who have been on antibiotics for other infections such as pneumonia or patients with surgical implants and prior deep wound infections who are on chronic antibiotic therapy. Theoretically, retrieval of a pathogen from the disc space or vertebral body may be compromised by previous or ongoing antibiotic treatment. However, we were unable to identify any high-quality randomized clinical trial comparing the culture results of the image-guided biopsy between patients who received empirical antibiotic treatment versus those who did not have any antibiotic treatment prior to biopsy.

There has been a general consensus of opinion that antibiotics should be withheld prior to biopsy of the site of suspected infection in an effort to improve the yield of culture [6,7]. A study by Rankine et al. found that the yield of biopsy in isolating the infecting organism was lower at 25% in patients who had received antibiotics compared to 50% yield in patients who had not received antibiotics [8]. It is important to note that not all studies agree with the notion of withholding antibiotics prior to biopsy of the infected site. A recent study by Sehn et al. [9] reported that four of 14 patients with a high suspicion for infection, who were confirmed to have been treated with antibiotics within 3 days of their biopsy, had positive cultures. The yield of culture was not different from the cohort of 92 patients who had not received antibiotics (28.6% vs. 30.4%, $p = 0.86$). Both of the reports were retrospective non-randomized studies with a relatively small sample size.

In the absence of randomized prospective data, and using the logic drawn from other fields of orthopaedic study related to this

issue, we recommend that empirical treatment with antibiotics be withheld in patients with suspected infection of the spine until biopsy of site of suspected infection can be carried out. There are, however, circumstances (such as situations involving critically ill patients and those with deteriorating neurological status) in whom antibiotics may be started prior to the performance of biopsy.

QUESTION 8: What is the incidence of infectious bacterial meningitis (PBM) following spinal surgery? Does the use of instrumentation affect this?

RECOMMENDATION: The incidence of PBM following spinal surgery varies from 0.1–0.4%. There is insufficient evidence to make any observations as to whether the use of instrumentation affects the incidence of PBM following spinal surgery.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

PBM is a potentially devastating complication following spinal surgery. It could occur after any primary elective spinal surgery with or without instrumentation, traumatic fracture-dislocation or surgical site infection after spinal instrumented surgery [1–3]. This also presents as a delayed complication after scoliosis surgery and through a dural tear with cerebrospinal fluid (CSF) leakage [4,5].

The early diagnostic differentiation from PBM and postoperative aseptic meningitis (PAM) is difficult and depends on CSF culture results [6–7]. The success in the treatment of patients with PBM depends on the stage of diagnosis, speed of diagnostic evaluation and appropriate anti-microbial and adjunctive therapy [8–9].

PBM is a potentially life-threatening infection with higher rates of mortality and significant disabling morbidity [9]. Pneumococcal meningitis is the most prevalent and is associated with a mortality of 30% [10]. PBM can also be caused by staphylococci [11], aerobic gram-negative bacilli (including *P. aeruginosa*) [12] and methicillin-resistant *Staphylococcus aureus* (MRSA) [13].

The incidence of PBM is rare after spinal surgery and is considered to be related to incidental durotomy [14]. Patients who have the triad of fever, neck stiffness and consciousness disturbance during postoperative period should be suspected and subjected to further evaluations [14]. In a large retrospective study, Lin et al. reviewed 20,178 lumbar spinal surgeries and reported a PBM rate of 0.10% [14]. Another retrospective study by Twyman et al. reported the incidence of PBM to be 0.18% after spinal operations with and without instrumentation [15]. The incidence could be as high as 0.4% after spinal surgery, when epidural abscess, subdural empyema, brain abscess, bone-flap infections and wound infections are combined [16].

In their sub-analysis, Lin et al. found that dural tears, pseudomeningocele and poor wound healing contributed to the majority of the complications [14]. The optimal management of PBM required reoperation to repair dural tears and administration of parenteral antibiotics [17]. The occurrence of pseudomeningocele is a sequela of dural tear, imperfect suture of the dura or fascia and inappropriate administration of antibiotics [14,18,19]. Zhang et al. reported surgical intervention to be an effective method of treating PBM where initial conservative measures failed. They proposed the idea that it is important to consider the possibility of PBM in any patient with CSF leakage after spinal surgery. They recommended early diagnostic imaging and CSF cultures to ensure prompt diagnosis and treatment [20].

Spinal instrumentation surgery usually involves longer operative time, greater blood loss and a higher incidence of subsequent SSI compared to decompression surgery alone. These features of spinal instrumentation surgery could influence the incidence of PBM. There is little literature examining the potential association of instrumentation with PBM with no supporting evidence linking the use of instrumentation to the incidence of infectious meningitis after spinal surgery [14,15,20]. Therefore, based on available evidence, it is not possible to link the use of instrumentation during spine surgery with PBM.

QUESTION 9: What are the early infectious complications after operations on the spine following the use of instrumentation?

RECOMMENDATION: Early infections are traditionally defined as those occurring within a month after surgery, typically becoming evident within two to three weeks of surgery. Recently, the definition has been broadened to include infection within 90 days of surgery.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 60%, Disagree: 20%, Abstain: 20% (Super Majority, Weak Consensus)

RATIONALE

Early infections are traditionally defined as those occurring within a month of surgery, typically becoming evident within two to three weeks of surgery. Recently the definition of early infection has been broadened to include infection within 90 days of surgery [1]. Surgical site infections (SSIs) and wound dehiscence are among the most common complications following spine surgery. It has been reported that the incidence of SSIs after adult spine surgery varies from 2–20% following instrumented procedures [2].

A study based on the American College of Surgeons' National Surgical Quality Improvement Program database reported that in a total of 99,152 spine surgery cases between 2012 and 2014, the overall wound complication rate was 2.2% with superficial SSI, 0.9% with deep SSI, 0.8% organ space SSI and 0.4% dehiscence: 0.3%. Of all the patients who experienced wound dehiscence, 46% had concomitant SSI. The average postoperative day of occurrence was 14 days with a standard deviation of 9 days (superficial SSI: 16 ± 8, deep SSI: 13 ± 10, organ/space SSI: 11 ± 10, dehiscence: 17 ± 8) [3].

Similar to other SSIs, early infections after spine surgery may present as pain, fever, erythema, swelling, warmth, tenderness and wound drainage. Local pain may herald the development of infection, particularly when it is escalating in nature. Wound drainage is common for both superficial or deep SSIs and may be present in up to 90% of patients [4].

Early postoperative spinal infections are most frequently due to relatively virulent pathogens such as *Staphylococcus aureus*, beta-hemolytic streptococci and aerobic gram-negative bacilli. *Staphylococcus aureus* is the most common bacteria responsible for early postoperative infection after spinal surgery [5–7]. The majority of the cases are due to methicillin-sensitive *Staphylococcus aureus* (MSSA), however the incidence of methicillin-resistant *Staphylococcus aureus* (MRSA) is escalating [8]. The majority of early infections are due to a single pathogen [9]. There has been an increase in the frequency of infections caused by gram-negative bacteria and other organisms such as *Pseudomonas aeruginosa*, *Escherichia coli*, Enterobacter and Acinetobacter [10–12].

Utilization of posterior instrumentation is well-recognized as a risk factor for the development of postoperative spinal wound infections. However, this finding is largely based on suboptimal retrospective analyses. Multiple factors increase the rates of infection following instrumented spinal surgery, such as increased wound exposure to air due to longer surgical time, greater soft tissue dissection, increased muscle/skin retraction, greater blood loss and potentially larger dead spaces [13–15].

However, anterior spinal exposures were reportedly correlated with a reduced risk of infection as they typically traverse relatively avascular tissue planes and avoid significant muscle dissection [16–19]. It is yet to be determined whether minimally invasive spine surgery is associated with lower infection rates versus open surgery following the use instrumentation [20–21], although a recent study involving 108,419 procedures reported that the use of a minimally invasive approach was associated with a lower rate of infection for lumbar discectomy (0.4% vs. 1.1%, $p < 0.001$) and for transforaminal lumbar interbody fusion (1.3% vs. 2.9%, $p = 0.005$) [22].

2.2. DIAGNOSIS: BIOMARKERS

Author: Maja Babic

QUESTION 1: Are there any diagnostic tools that are useful for early surgical site infection (SSI) detection following spinal surgery? Does this differ whether or not there was instrumentation?

RECOMMENDATION: C-reactive protein (CRP) can be used to diagnose early SSI following spinal surgery.

A failure of CRP to decline or a second rise on postoperative days four to seven is a sensitive marker for infection following spine surgery, including both instrumented and non-instrumented spine surgery.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 86%, Disagree: 7%, Abstain: 7% (Super Majority, Strong Consensus)

RATIONALE

In a prospective study of 73 consecutive patients undergoing spinal decompression with and without instrumentation, inflammatory markers were assessed. They showed that following uncomplicated spinal surgery, CRP levels rise sharply, peaking on the second postoperative day [1]. Peak CRP values after instrumented lumbar surgery are significantly higher than those after non-instrumented spine surgery, but decline with the same half-life [1]. CRP was superior to erythrocyte sedimentation rate (ESR) in early detection of infections after cervical spine surgery, as shown in a prospective study of 51 cases [2]. In another large, prospective trial including 400 elective discectomy cases, CRP was shown to be a reliable, simple and economical screening test for infectious complications after lumbar microdiscectomy, superior to classical laboratory parameters. The sensitivity of serial CRP testing was calculated to be 100% with 95.8% specificity. ESR and white blood cell measurements fail to reach distinctive significance in diagnosing early SSI [3].

Author: Maja Babic

QUESTION 2: When do common blood biomarkers such as C-reactive protein (CRP), erythrocyte sedimentation rate (ESR) or Procalcitonin normalize after spine surgery?

RECOMMENDATION: Following spinal surgery with or without instrumentation, CRP values peak on days 2-3 postoperatively and normalize within 14 days. ESR also normalizes within 14 days.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 50%, Disagree: 29%, Abstain: 21% (NO Consensus)

RATIONALE

Multiple prospective studies suggest that CRP values peak within 2-3 days postoperatively (peak levels depend on extent of surgery, levels involved, etc.) and decrease back to baseline within 14 days. A rapid decline of CRP postoperatively is interrupted if postoperative infection sets in and a secondary rise occurs [1,2]. Prospective studies have shown that ESR peaks by day four following spinal surgery and in the majority of cases normalizes by two weeks postoperatively [3]. However, monitoring of CRP level was found to be superior to that of ESR for early detection of infections after cervical spine surgery in a series of 51 cases of anterior cervical fusion [4]. A second rise of CRP and ESR or failure to decline is an indicator of potential surgical site infection [5,6]. Limited data is available on the value of Procalcitonin [7].

Author: Maja Babic

QUESTION 3: Is there a role for the use of serum biomarker for the diagnosis of spinal surgical site infection (SSI)?

RECOMMENDATION: Yes, C-reactive protein (CRP) is a predictable, reliable and economical screening tool for early infectious complications following spine surgery. Erythrocyte sedimentation rate and white blood cell count have nonspecific kinetics that are less helpful in identifying early SSI.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 67%, Disagree: 25%, Abstain: 8% (Super Majority, Weak Consensus)

RATIONALE

In a prospective study involving 348 patients who underwent decompression laminectomy, postoperative CRP was helpful in detecting early infectious complications following surgery. As a predictor for early wound infection, the sensitivity, specificity, positive predictive value and negative predictive value for abnormal CRP responses were calculated as 100%, 96.8%, 31.3% and 100%, respectively. Close observation of the surgical site is recommended in patients with abnormal CRP values at day five or seven postoperatively, namely for failure to decline or a secondary rise [1].

Of 149 patients undergoing elective spine surgery, 20 developed infectious SSI complications. Postoperative CRP kinetics were predictable and indicative of early infection where a secondary rise or lack of CRP decrease had a sensitivity, specificity, positive predictive value and negative predictive value of 82%, 48%, 41%, and 86% for infectious complications, respectively [2].

Out of 400 patients undergoing lumbar micro-discectomy over a 15-month period, 9 developed infectious complications related to surgery. CRP values were shown to be a reliable and economic screening tool in identifying the patients at risk with a sensitivity for serial CRP testing (day one and five postoperatively) calculated as 100% with a specificity of 95.8% [3].

Author: Bryan Alexander

QUESTION 4: Is there a role for molecular techniques such as polymerase chain reaction (PCR) or next-generation sequencing (NGS) for the diagnosis of spinal surgery infection? If so, in which group of patients should this be done?

RECOMMENDATION: It is reasonable to selectively incorporate these diagnostic modalities as an adjunct to standard methodologies where there is a history or high pre-test probability for culture negative infection.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 71%, Disagree: 14%, Abstain: 15% (Super Majority, Strong Consensus)

RATIONALE

Successful management of periprosthetic joint infections (PJI) is significantly enhanced with a prompt and accurate microbiological diagnosis. Conventional culture methods for diagnosis of PJI can be compromised and complicated by early antibiotic treatment, heterogeneity of surgical sampling, fastidious microorganisms difficult to grow in culture and non-planktonic pathogens utilizing biofilms. Therefore, modern molecular microbiologic methods have naturally been seen as very promising for increasing diagnostic yield in these circumstances. Technologies that have more recently been applied to PJI generally include ribosomal RNA sequencing, species-specific and multiplex PCR and matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS).

Specifically, with respect to spinal and vertebral infections, these varied technologies have demonstrated success in leading to an etiologic diagnosis. These methods have been used to identify a variety of pathogens, including *Staphylococcus spp.* [1–3], *Streptococcus spp* [3,4], *Enterococcus spp.* [4], Enterobacteriaceae [3–5], *Brucella spp.* [6], *Mycobacterium spp.* [2], atypical bacteria (*T. whipplei*) [7], *Mycoplasma spp.*) [8], anaerobes (*Clostridium spp.*) [3], *Fusobacterium spp.*) [4,9] and fungi (*Aspergillus spp.*) [10].

By far, the most experience with these techniques for spinal infections is in the diagnosis of Pott's disease (*Mycobacterium tuberculosis*) [2,6,11–15]. These reports generally demonstrate a high sensitivity and specificity of PCR modalities, though many of these studies have been completed in tuberculosis endemic geographic areas with likely higher inoculum infections and a well-defined pre-test probability.

False positive results from dead or colonizing/contaminating bacteria is a concern with these tests, and studies evaluating the appropriate number of samples to optimize sensitivity and specificity specific to these molecular methods are limited and not specific to spinal infections [16]. Another important concern with molecular techniques for PJI diagnostics is that they do not commonly allow for susceptibility testing to appropriately target antimicrobial therapy. Certain resistance mechanisms, such as methicillin resistance in *S. aureus* [1,17,18] or rifampin resistance in *M. tuberculosis* [12], are reliably expressed if genetically detected. This is not the norm, however, as resistance expression is generally a complex phenotype determined by multiple factors. Care should be taken not to overly rely on non-susceptibility-generating techniques, as they can just as easily lead to long courses of overly-broad therapy, as can no etiologic diagnosis at all, undermining patient safety and important principles of antimicrobial stewardship. In addition, it has been noted that utilizing molecular methods as an adjunct to and in combination with standard culture methodologies often serves to improve overall diagnostic yield [3].

A few studies have attempted to establish test sensitivity and specificity data when compared to routine culture for bone and joint specimens in general [4,15,19–23], however these efforts are limited by lack of a true gold standard diagnostic method for comparison, the variety of testing methodologies clinically employed and non-standardized clinical criteria for utilization of these methods. Predictably, results vary widely, with sensitivities reported between 50–92% and specificities between 65–94% [20]. No studies investigating sensitivity and specificity of these techniques specific only to spinal post-surgical infections have yet been reported. Therefore, an evidence-based evaluation of the appropriate clinical criteria for utilization of these techniques in spinal surgery patients is not currently possible. One study proposed a strategy for routine collection and potential use of molecular diagnostics in PJI [24]. There is no data investigating the cost effectiveness for any diagnostic schema incorporating molecular methods, however given their positive proof-of-concept and the significant clinical impact of spinal post-surgical infections, it seems reasonable to selectively incorporate the use of molecular methods into situations where there is a high pre-test probability for indolent or culture-negative infection as further studies are done to standardize their use.

QUESTION 5: For which investigations should samples obtained by image-guided biopsy be sent?

RECOMMENDATION: A priority should be placed on obtaining bacterial cultures and pathohistology. In the appropriate epidemiological setting, mycobacterial, fungal and brucellar cultures can be considered.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 93%, Disagree: 0%, Abstain: 7% (Super Majority, Strong Consensus)

RESPONSE

There is limited data available in the literature to help establish clear evidence-based parameters for treatment. However, there are society-based clinical guidelines such as the 2015 Infectious Diseases Society of America (IDSA) clinical practice guidelines for the diagnosis and treatment of native vertebral osteomyelitis in adults, which provide assistance in decision-making. Highlights from this statement recommend the acquisition of image-guided aspiration biopsy in patients with suspected vertebral osteomyelitis when a microbiologic diagnosis for a known associated organism has not been established by blood cultures or serologic tests. Further, they recommend for the addition of fungal, mycobacterial or brucellar cultures on image-guided biopsy and aspiration specimens in patients with suspected vertebral osteomyelitis if epidemiologic, host risk factors or characteristic radiologic clues are present, or if testing to appropriately stored bacterial specimens reveal no growth [1].

There is some data to suggest that standard samples should be sent for both microbiology and pathohistology. Pathologic evaluation is meaningful, particularly in culture negative cases where the presence of leukocytes can indicate pyogenic osteomyelitis, or visualization of granulomas can suggest mycobacterial infection or brucellosis [2]. Pathology can also support ruling out diagnoses like ankylosing spondylitis, hemodialysis-associated spondyloarthropathy or neuropathic Charcot joint deformities [3]. Furthermore, crystal deposits can aid in the diagnosis of pseudogout [4].

QUESTION 6: How many intraoperative tissue samples should be sent for culture in suspected spinal surgery infection?

RECOMMENDATION: With the currently-available evidence, it is recommended that at least three to five tissue samples be sent for culture in cases of suspected spinal infection. In the setting of instrumentation, we recommend additional techniques, such as vortexing and sonification, to increase the yield of culture samples.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 80%, Disagree: 13%, Abstain: 7% (Super Majority, Strong Consensus)

RATIONALE

Turnbull described surgical site infections (SSIs) in spinal surgery in 1953, noting three cases of deep infection of the disc after discectomy as well as significant morbidity that followed [1]. While clinically these cases presented as infection, Turnbull reported them as "presumed" infection because culture of the causative organism was not obtained. Since his work, the incidence of SSI following spine surgery has been studied extensively, with reported incidences ranging from 0.2–15%, varying widely based on underlying pathology and procedure type, with revision procedure, fusion, implantation, and traumatic injury carrying the greatest risk [2–6]. The most common causative culprits are *Staphylococcus* species, including methicillin-resistant *S. aureus* (MRSA) [3,6–9], although less virulent organisms such as *Propionibacterium acnes* can also occur, particularly in revision cases without a definitive preoperative diagnosis of infection [10–12]. Prior to obtaining intraoperative cultures, some suggest computed tomography-guided aspiration, although this practice has been shown to have low sensitivity [13,14].

The evidence for the optimal number of specimens to obtain in cases of suspected spinal infection is sparse. In their study of patients undergoing Cotrel-Dubousset instrumentation, Bemer et al. evaluated cases of *Cutibacterium acnes (C. acnes)* infection, noting that in earlier years of the study one to two samples for culture were obtained, whereas later in their series they had increased that number to four to six samples. Based on their experience and the difficulty in diagnosis of *C. acnes*, these studies recommend that at least four deep tissue samples be taken to facilitate interpretation of the cultures [11].

In the setting of implantation, one major challenge is that peri-implant cultures may not be accurate and it can be difficult for biofilm cultures to grow [15]. In their study of removed spinal implants in the setting of infection, Sampedro et al. report using a technique of vortexing and sonification followed by culturing, which resulted in significantly increased sensitivity compared to simply taking two to nine peri-implant tissue samples [12]. Finally, in a study assessing specimens taken from orthopaedic device revision surgery (5.1% spine cases), the standard procedure was to obtain three to six (mean: four) samples per case, including specimens from the inflammatory membrane around the implant, joint capsule (as applicable) and any macroscopically suspect tissues [16]. In this study, a threshold of at least three positive samples with identical microorganisms was used for diagnosis. The authors note that this definition is strict compared to other studies that use two identical culture-positive specimens for diagnosis and report that their findings would not have differed had they used a lower threshold of two.

It is important to remember that positive cultures may not represent true infection and should be interpreted in the overall context of the individual patient and clinical picture. Gelalis et al. studied bacterial contamination during simple and complex spinal procedures in 40 patients, taking culture swabs during each case, first from the sterile transparent sheet over the operative site at the start of the case, followed by hourly samples from the surgical wound. The authors reported that none of the patients with positive cultures developed clinical signs of infection or required antibiotics, whereas three patients with negative cultures developed postoperative infection [17].

Though there is little guidance in the spine literature, the data in arthroplasty may help to guide future practices. In a study looking at revision hip and knee arthroplasty, Atkins et al. found that the presence of three or more culture-positive specimens was highly predictive of infection (likelihood ratio, 169; sensitivity, 66%; specificity, 99.6%), whereas a single culture-positive specimen was found to have low diagnostic value (likelihood ratio, 0.7; post-test probability of infection, 10.6%) [15]. In their study, the authors determined that five or six samples are required to produce excellent sensitivity and specificity. Similarly, in a study of periprosthetic joint infection caused by MRSA, Parvizi et al. took five cultures in each case [18]. In accordance with the evidence, the Workgroup of the Musculoskeletal Infection Society recommends that three to five culture samples be taken and incubated in an aerobic and anaerobic environment [19].

There is little evidence regarding the optimal number of samples to obtain in the setting of suspected spinal surgery infection. Given the limited data that is available in the spine literature, we conclude that taking at least three to five tissue samples represents current best practice. In the setting of instrumentation, we recommend additional techniques, such as vortexing and sonification, to increase the yield of culture samples.

2.3. DIAGNOSIS: IMAGING

Authors: Chad Craig, Brandon Carlson

QUESTION 1: What is the optimal mode of imaging in the diagnosis of spine infections? If magnetic resonance imaging (MRI) is contraindicated, what imaging modality should be used?

RECOMMENDATION: MRI remains the gold standard for the diagnosis of spinal infection, with sensitivity and specificity above 90%. In the presence of MRI contraindications, consider a combination of modalities, such as computed tomography (CT), positron emission tomography-CT (PET-CT), and single photon emission CT (SPECT)+67Gallium or Gallium-67.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Plain radiography should be the initial exam performed for all patients with non-specific spine or back complaints. In patients with spinal infections, early radiographic findings will occur two weeks to three months after the onset of symptoms. Plain radiographic findings characteristic of a spinal infection include disc space narrowing, end plate irregularity, loss of end plate contour, subchondral defects and/or hypertrophic or sclerotic bone formation. Disc space narrowing has been reported as the most consistent plain radiographic finding occurring in 74% of cases [1]. Late plain radiographic findings include vertebral body collapse, pathologic fractures, segmental kyphotic collapse and/or bony ankylosis. Plain radiography has reported sensitivity of 82% and specificity of 57 to 59% in subjects with pyogenic spondylodiscitis [2,3]. While this modality may not provide the highest level of diagnostic quality, it can give clinicians an understanding of global and focal alignment, deformities associated with infectious processes and mechanical stability [4]. Plain radiographs may also be used for post-treatment surveillance and/or monitoring for potential late deformity or instability associated with these diseases.

CT is an advanced imaging technique that can be utilized for diagnosing spinal infections. It provides higher resolution and multiplanar imaging of the bony architecture. CT findings characteristic of spinal infections can include cystic bony changes, gas within vertebral discs, endplate osteolysis surrounding the vertebral disc and/or paravertebral soft tissue swelling or abscess formation [5–7]. The addition of contrast media during computed tomography can help better delineate the edges of paravertebral abscesses and edematous musculature [5–7]. In cases with neurological deficits or new onset radiculopathy, post-myelogram CT scan can provide excellent detail of the spinal canal and poten-

tial epidural and/or subdural abscesses [8]. In cases where myelogram is performed, it is recommended to analyze the cerebral spinal fluid to rule out meningitis [9]. SPECT is a scintigraphic CT modality that has increased bone contrast resolution, and when combined with technetium or gallium, has high sensitivity and diagnostic accuracy for spinal infections. SPECT with gallium has been shown to be superior to SPECT + technetium and is now the recommended imaging modality for patients with MRI contraindications [10].

MRI remains the gold standard for early and accurate diagnosis of spinal infections [11–20]. MRI has a reported sensitivity of 96%, specificity of 93% and diagnostic accuracy of 94% [18]. MRI has higher accuracy for differentiating degenerative and neoplastic conditions from infections in patients presenting with severe back pain of unknown etiology [11]. While MRI may provide the most detailed information for diagnosing possible infections, it does not reduce the need for tissue biopsy for histological analysis. T1-weighted and T2-weighted sequences should be obtained. The most common MRI findings consistent with spinal infections show decreased vertebral body intensity with poor differentiation between the disc and body on T1-weighted images and increased disc space intensity with marked decreased vertebral body intensity on T2-weighted images [16,18,20]. Utilizing gadolinium contrast can enhance MRI ability to detect and delineate epidural abscesses [21]. All publications consider MRI the gold standard imaging modality for spinal infections and recommend it should be used in all patients without MRI-specific contraindications.

Radionucleotide studies are another modality that is useful for diagnosing spinal infections. These include technetium-99m bone scans, gallium-67 scans, and indium-111 labeled leukocyte scans. Pathologic changes have been shown to appear sooner on radionucleotide studies compared to plain radiography [22–27]. Gallium scans have demonstrated earlier diagnosis of disc-space infections compared to technetium scans and have a reported sensitivity of 89%, specificity of 85% and accuracy of 86% [22,23,28]. Technetium-99m scans have a reported sensitivity of 90%, specificity of 78% and accuracy of 86%.18 When both gallium and technetium scans are performed together, the sensitivity is increased to 90%, specificity 100% and accuracy is 94%.18

Indium-111 scans are known to be sensitive for appendicular skeletal infections, however sensitivity is low in the spine [29–32]. In patients with low-virulence chronic infections, indium-111 scans can provide false-negative results due to white blood cell pooling with any inflammatory process [31]. Indium scans may also result in false-positive results in neoplastic conditions. One important advantage of indium-111 scans is the ability to differentiate non-infectious conditions such as hematoma or seroma in patients with unclear soft tissue etiology. This may be a valuable diagnostic step when investigating possible postoperative infections. Overall, most publications endorsed less utility for radionucleotide studies versus MRI. However, in patients with MRI contraindications, technetium-99m combined with gallium-67 studies is another method that has high sensitivity, specificity and diagnostic accuracy similar to MRI.

There is no single diagnostic test with 100% accuracy for these devastating diseases. A full diagnostic workup includes laboratory studies, blood cultures, imaging and tissue histological analyses. It is generally accepted that plain radiography should be the first imaging study obtained, however, diagnostic sensitivity is low. MRI remains the gold standard with the highest sensitivity, specificity and accuracy compared to other modalities. In the presence of MRI contraindications, clinicians should utilize SPECT+gallium-67 or gallium-67 and technetium-99 combined scans to achieve similar diagnostic accuracy as MRI.

QUESTION 2: Is there a role for computed tomography (CT) scan with contrast in the diagnosis of spinal infections in patients who cannot undergo magnetic resonance imaging (MRI)?

RECOMMENDATION: Although evidence is limited for the routine use of CT scan with contrast, there is a role for it to be used in the presence of spine infection where MRI is contraindicated or when other advanced imaging is not available

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Although there is growing evidence of the safety of MRI in the presence of implanted metallic devices [1], obtaining such a study may not always be possible. CT with either extradural or intravenous contrast can be used to identify spine infections.

Prior to the wide adoption of MRI, CT myelography was commonly used to diagnose extradural compressive pathology such as epidural abscesses [2]. The use of this invasive investigation in the setting of postoperative spine epidural abscess has not been studied. However, it can be assumed that the accuracy will be lower due to metal artefact [3].

The role of CT with intravenous contrast in the postoperative setting is unclear and has not been directly studied. CT is most useful in identifying implant and bony related complications such as implant loosening, endplate erosion and destruction. The addition of contrast provides information on paraspinal soft tissue involvement, phlegmon or abscesses albeit with lower sensitivity and specificity when compared to MRI [4].

QUESTION 3: Is there a role for nuclear imaging (e.g., positron emission tomography scan (PET)) in the diagnosis of spinal infections?

RECOMMENDATION: PET scan, preferably PET-computed tomography (PET-CT), can be used as an adjunct to magnetic resonance imaging (MRI) to diagnose spinal infections when an MRI cannot be performed or is inconclusive.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

At the present time, MRI is the imaging test of choice for diagnosing spondylodiscitis (SD). This study should be performed when SD is suspected to avoid the morbidity and mortality associated with a delay in diagnosis. MRI is a favored choice as part of an infectious work up due to its lack of ionizing radiation, multi-planar capability, superior soft tissue contrast and ability to evaluate the neural structures. It has a sensitivity and specificity of 97% and 93% respectively. Ultimately, its accuracy in diagnosing SD is 94% [1–3]. A typical protocol should include T1- and T2-weighted sequences with gadolinium. T2 and post-gadolinium T1-weighted sequences should also be performed with fat suppression to increase the sensitivity of identifying pathology [4,5]. Furthermore, MRI allows for the evaluation of bone marrow edema and disc space inflammation, as well as paraspinal and epidural soft tissue involvement. Gadolinium is helpful in differentiating phlegmonous changes versus abscess formation.

Fluorine-18-fluorodeoxyglucose (18F-FDG) is the radionuclide-imaging test that can be a useful compliment to MRI. The role of 18F-FDG in the diagnosis of SD has been extensively investigated [6–13]. It has shown acceptable levels of sensitivity and specificity and is useful when MRI cannot be performed or is inconclusive. In addition to its value for diagnosing spondylodiscitis, 18F-FDG can be utilized to monitor response to treatment. Gallium-67-SPECT/CT is an acceptable alternative when 18F-FDG is not available [14].

Author: Susana Núñez-Pereira

QUESTION 4: How can postoperative infections be distinguished from normal postoperative changes on magnetic resonance imaging (MRI)?

RECOMMENDATION: The presence of an abscess in the back muscles or posterior site, confirmed by gadolinium enhancement, is the most frequently-reported change on MRI of patients with surgical site infection (SSI). The presence of a collection of fluid outside the head of the pedicle screws is another sign of SSI.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 71%, Disagree: 8%, Abstain: 21% (Super Majority, Strong Consensus)

RATIONALE

A search was conducted using the MeSH terms "spine AND MRI AND surgical site infection." The initial search yielded 149 references, and after screening, 13 abstracts remained. However, only three studies assessed the use of MRI for postoperative spine infections and were found eligible.

Kanayama et al. retrospectively used MRI in 20 patients with surgical site infections after instrumented spinal surgery [1]. In their series they considered two markers for diagnosing SSI: (1) the presence or absence of osteomyelitis at the instrumented vertebra and (2) the presence or absence of intervertebral abscess. All 20 patients had a confirmed SSI, but in 7 MRIs it was considered negative. The study mainly aimed to assess the utility of MRI to confirm the severity of the infection. Using the above-mentioned criteria, they tried to predict the need for implant removal. However, MRI was not evaluated as a diagnostic tool for assessing the presence or absence of infection.

Kim et al. reviewed 43 patients with MRI after SSI [2]. First, they divided their infections on an anatomical basis, assessing if it affected only the posterior region (31 cases), only the anterior area or both posterior and anterior regions [2]. In addition, they looked for abscess in different spinal locations (posterior epidural space, laminectomy site, back muscles, subcutaneous fat layer, paravertebral space, psoas muscle and anterior epidural space). They also evaluated the presence of osteomyelitis of the vertebral body and discitis. The most frequent findings were abscesses in the back muscles in 40 patients (93%), abscesses in the laminectomy site in 29 (67.4%) and in the subcutaneous fat layer in 27 (62.8%). All abscesses were identified by the presence of peripheral rim or diffused enhancement of adjacent soft tissue after administration of intravenous gadolinium.

They did not compare their findings with those of patients without confirmed SSI. The authors concluded that for diagnosing infection, the posterior surgical field was more important than the vertebral body or the disc area. This conclusion supports the findings of the previous study by Kanayama, in which seven patients with SSIs did not show involvement of the vertebral body or the disc area.

Finally, Kimura et al. published a comparative study on postoperative MRI including 17 patients with a deep SSI and 64 non-SSI controls who had an MRI examination within 4 weeks after surgery [3]. Their investigation focused on the "pedicle screw fluid sign" (PS fluid sign) and did not search for other signs of infection. The PS fluid sign refers to the collection of fluid outside the head of a pedicle screw, suggesting the presence of an abscess on axial MRI scans. The authors observed that fluid collections medial to the pedicle screw head are not infrequent. They considered that when the collection expands outside the head of the screw into the paravertebral

muscles, it is likely to be an abscess. In their view, artifacts have little effect on the area outside the screw head, compared with the inside. In their study, this sign was positive in 15 of 17 deep SSI infections and only in 7 of 64 patients without infection. Sensitivity was 88.2%, specificity 89.1%, positive predictive value 68.1% and negative predictive value 96.6%.

In conclusion, abscesses in the back muscles, laminectomy site and subcutaneous fat layer, after administration of gadolinium were the most common findings related with surgical site infection. In addition, the PS fluid sign had a sensitivity of 88.2% and specificity of 89.1%.

Treatment

3.1. TREATMENT: GENERAL PRINCIPLES

Author: Claus Simpfendorfer

QUESTION 1: Can a non-surgical approach be used to treat postoperative spine infections? If so, what factors predict a successful outcome?

RECOMMENDATION: Postoperative spine infections should be treated with irrigation and debridement (with or without implant removal) followed by appropriate antibiotic therapy. Antibiotic suppression without surgical intervention should be attempted in cases where the patient is not a surgical candidate, or in attempt to achieve spinal fusion prior to implant removal.

LEVEL OF EVIDENCE: Strong

DELEGATE VOTE: Agree: 80%, Disagree: 7%, Abstain: 13% (Super Majority, Strong Consensus)

RATIONALE

Postoperative surgical site infections are a major complication that occur between 1 and 12% of all spinal surgeries [1–3]. Treatment varies based on general location in relation to superficial, or deep to the muscular fascia, and the time from initial surgery, with early infections occurring before 90 days and late infections occurring after 90 days.

In the case of superficial wound infections, local debridement, healing by secondary intention and a short course of antibiotics is usually sufficient [4]. Deep surgical site infections, on the other hand, require aggressive irrigation and debridement with or without implant removal. The retention of hardware predominantly depends on if the infection is early or late. Several studies have demonstrated that hardware can be retained successfully following aggressive irrigation and debridement in the setting of early infection, except in cases where the implants are loose or there is bony involvement [5–9]. Optimal treatment of delayed infections is aggressive irrigation and debridement with implant removal [10–12]. In the cases where spinal fusion has been achieved, implant removal is routinely performed. However, in cases of fusion failure or pseudoarthrosis, surgical options include aggressive debridement and irrigation with attempted implant retention, implant removal with primary or delayed reimplantation or implant removal without reimplantation [6,13–16].

Antibiotic suppression without surgical intervention is attempted in cases where the patient is not a surgical candidate, or in an attempt to achieve spinal fusion prior to implant removal.

QUESTION 2: When should patients with suspected infections of the spine be referred to an infectious disease department?

RECOMMENDATION: There is no data on the timing or need for a referral to an infectious disease department. We support a multidisciplinary approach to managing clinical spine infections.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Only one paper has addressed the collaboration with an infectious disease-specialized team in order to improve outcomes for patients with spinal surgical site infections (SSIs). The paper is a retrospective study reporting on 40 patients, none of whom needed implant removal [1]. The paper didn't report on the exact timing when collaboration started, but reported three main advantages related with this collaboration:

1. Efficient detection of auxiliary bacteria (reached 88%)
2. Early treatment with antibiotics
3. Appropriate duration of administration of antibiotics

There were no other papers which discussed this issue, and all subsequent searches on related articles yielded no more information on the matter.

From a theoretical point of view, referral, or at least counselling by an infectious diseases specialist, might have some advantages. Antibiotic treatments are more complex today and only specialists are adequately up-to-date on the issue. The appropriate treatment choice might be difficult in patients with allergies, multi-resistant smears or simply a low tolerance for the medication. Adjusting the choice of antibiotic, taking into account side effects and tolerance, will very likely improve compliance, which is paramount in reaching a successful treatment outcome.

QUESTION 3: Which patients with vertebral osteomyelitis (VO) are suitable for outpatient management? Does any criteria exist to aid in this decision-making?

RECOMMENDATION: There are no studies aiming to identify which patients diagnosed with VO can be treated on an outpatient basis.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 93%, Disagree: 7%, Abstain: 0% (Super Majority, Strong Consensus)

RATIONALE

VO, also known as spondylodiscitis, describes an infection of the vertebrae and intervertebral disc. By comparison, discitis describes infection limited to the intervertebral disc, however there are many who consider discitis and VO to be different stages of the same disease process. VO can arise from hematogenous seeding, contiguous spread from infection in adjacent soft tissues or direct inoculation during spinal surgery or procedures (i.e., epidural). Management of native vertebral osteomyelitis (NVO) depends on the location of the infection, disease progression and the patient's general condition including age and comorbidities.

Conservative treatment is reasonable in the early stages with no or minor neurologic deficits or in the case of severe comorbidities. However, in cases of doubt, surgical treatment should be considered. Both options require a concomitant antimicrobial therapy, initially applied intravenously and administered orally thereafter [1]. To date, there is no consistent data from randomized controlled trials to guide the optimal duration and appropriate route of antibiotic therapy. Although the optimal duration of antibiotic therapy remains controversial, it should never undercut six weeks [2]. Recent Infectious Diseases Society of America (IDSA) guidelines for the diagnosis and treatment of NVO in adults include evidence and opinion-based recommendations for the management of patients with NVO treated with antimicrobial therapy, with or without surgical intervention, but do not address the issue of which patients affected by NVO can be treated on an outpatient basis [3,4]. The extent of pursuing spinal biopsies to determine etiology, antimicrobial therapy, response to treatment and preference for surgical techniques and timing all vary widely in clinical practice with heterogeneous studies limiting comparisons. Surgery, rather than conservative approaches, is being proposed as the default management choice because in carefully-selected patients it can offer faster reduction in pain scores and improved quality of life [5–9]. Due to a

heterogeneous and often comorbid patient population and the wide variety of treatment options, no generally applicable guidelines for VO exist and management remains a challenge.

The goals of treatment include establishing a diagnosis and identifying the pathogen, eradicating the infection, preventing or minimizing neurologic involvement, maintaining spinal stability and providing an adequate nutritional state to combat infection. Often, this can be accomplished with non-operative approaches.

The mainstay treatment of pyogenic infections of the spine remains antibiotic therapy and immobilization with a proper orthosis. If nonsurgical treatment fails, however, surgical intervention may be required. Surgery is indicated in the following circumstances: to obtain a bacteriologic diagnosis when closed biopsy is negative or deemed unsafe, when a clinically significant abscess is present (spiking temperatures and evidence of sepsis), in cases of refractory to prolonged non-operative treatment where the sedimentation rate remains high or pain persists, in cases of spinal cord compression causing a neurologic deficit and in cases of substantial deformity or vertebral body destruction, especially in the cervical spine. Alton et al. reported that 75% of patients with an epidural abscess in the cervical spine who underwent medical management failed and that medical management failure was associated with a significantly increased risk of neurologic injury [10]. Patel et al. reported on 128 patients with an epidural abscess and found that 41% failed medical management. However, there were significant predictors of medical failure [11]. Four key predictors were identified, including diabetes mellitus, C-reactive protein (CRP) greater than 115, white blood cell count greater than 12.5 and positive blood culture. Patients with none of the aforementioned parameters only failed 8.3% of the time. Those with one parameter failed 35.4% of the time, those with two parameters failed 40.2% of the time and patients with three or more parameters failed 76.9% of the time.

Once the antibiotic is prescribed by oral route, if the patient is stable, the treatment could be administered in an outpatient setting. Several studies described a successful switch to oral antibiotics after 10 days, using oral agents with a high bio-availability and tissue penetration (i.e., fluorquinolones, rifampin, fusidic acid and clindamycin) [12–15]. A retrospective analysis of all patients diagnosed with NVO, at the University Hospital of Basel, Switzerland, concluded that switching to an oral antibiotic regimen after two weeks of intravenous treatment may be safe, if CRP has decreased compared to baseline CRP and epidural or paravertebral abscesses of significant size have been drained [16]. Importantly, these results do not extend to patients with endocarditis, surgical site infection, and/or vertebral implants. Also, positive blood cultures, neurological abnormalities and staphylococcal infections (compared with negative microbiology) are associated with longer intravenous courses [17].

Outpatient parenteral antibiotic therapy (OPAT) has become an option allowing for early discharge of hospitalized patients who have infections without a reliable oral alternative and requires lengthy antibiotic therapy. It provides numerous benefits, some of the most remarkable being that OPAT permits early discharge and reduces costs, avoids hospitalization trauma in children or immobilization syndrome in the elderly and reduces nosocomial infections by multidrug resistant organisms [17]. OPAT also allows for self-administration of antibiotics using elastomeric pumps [18,19]. Different retrospective studies and case series have reviewed the experience with OPAT in several countries [17,19–27]. β-Lactam antibiotics are commonly used in OPAT with higher treatment success among those treated with ceftriaxone and ertapenem, while oxacillin was associated with a higher rate of antimicrobial discontinuation because of antimicrobial-related complications [17,20,26]. Other alternatives are teicoplanin, telavancin or daptomycin in the case of gram-positive infections [17,25,28]. All this data regarding OPAT confirms that infection management in an outpatient setting is safe, clinically efficacious, and acceptable for treating a wide range of infections with high levels of patient satisfaction and substantial cost savings. Therefore, OPAT could be considered an effective alternative for appropriately selected elderly patients with vertebral osteomyelitis.

Authors: Chad Craig, Dolors Rodriguez-Pardo, Evan Sheha

QUESTION 4: What is the optimal treatment of spinal infections caused by *Propionibacterium acnes* (*P. acnes*)?

RECOMMENDATION: When possible, patients should undergo complete removal of implants after *Cutibacterium acnes* (*C. acnes*) (formerly *P. acnes*) infection, especially in the setting of latent infection. Antibiotic regimens typically involve specific parenteral antibiotics for a period of greater than two weeks, with the most common antibiotic duration being six weeks of multiple parenteral and/or oral agents. However, the duration of antibiotic treatment is highly variable. It is unclear in which setting patients may be successfully treated with antibiotic therapy alone and instrumentation may be retained. Penicillin is currently the standard of care, but other non beta-lactam antibiotics should be considered based on the susceptibility profile.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 73%, Disagree: 7%, Abstain: 20% (Super Majority, Strong Consensus)

RATIONALE

P. acnes is an anaerobic, gram-positive bacillus existing as normal flora of the skin and sebaceous glands and was originally considered a common contaminant of blood cultures as well as an uncommon cause of brain, pulmonary and dental infections [1]. *C. acnes* infections are commonly thought to originate from patient skin approximation with surgical sites, are frequently poly-microbial, require an extended incubation period in culture media for diagnosis and form a resistant biofilm, making treatment with antibiotics alone difficult [2–4].

P. acnes infection of the spine was first reported as an etiology of spine infection by Serushan et al. in 1982 [5]. The patient presented with osteomyelitis of the cervical spine and was treated with 40 days of intravenous penicillin with resolution of his fever and neck pain. *C. acnes* has subsequently been implicated in vertebral osteomyelitis and discitis and may present with insidious onset of back pain, fever and/or neurologic symptoms, with treatment typically involving administration of parenteral antibiotics. Additional debridement or percutaneous drainage of abscesses occurs in rare cases [6–8]. Duration of antibiotics ranged from 2-28 weeks in one series, and typically involved multiple agents due to the frequency of co-infection with other pathogens including *Staphylococcus,* Lactobacillus and Enterococcus species [9].

Tsai et al. reported on successful treatment of two cases of *C. acnes* osteomyelitis of the cervical spine with anterior debridement, decompression and fusion with autograft and treatment with a combination of oral and parenteral antibiotics for 6-16 weeks [10]. Overall, the decision to treat *C. acnes* vertebral osteomyelitis and discitis with surgery, antibiotics or a combination of these approaches has been made on a case-by-case basis. No well-defined, widely-applicable treatment regimen was identified in the literature.

C. acnes also frequently presents as a delayed infection after spinal instrumentation, which has been attributed to its low virulence and slow growth rate, and is common in instrumented pediatric scoliosis surgery [4,11–17]. Viola et al. reported a series of eight patients with delayed infection, one of which had *C. acnes* infection and was treated with irrigation and debridement, removal of instrumentation and six weeks of cefotetan with good results and no loss of balance or alignment at midterm follow-up. Of 23 patients with delayed infections after posterior TSRH instrumentation, Richards and Emara found that the causative agent in delayed infections was *C. acnes* in 12 (52.1%). Patients underwent removal of instrumentation with either primary or delayed closure and parenteral antibiotics (two to five days) followed by a course of oral antibiotics for an additional two to four weeks [18]. Tribus reported on a delayed infection with *Staphylococcus epidermidis* and *C. acnes* resulting in laminar erosions seven years after TSRH instrumentation. The patient was treated with removal of instrumentation and seven weeks of intravenous vancomycin and oral rifampin with resolution of pain and infection [12]. In cases of late implant infections, successful treatment typically involved implant removal and greater than two weeks of a combination of parenteral and oral antibiotics.

In the largest single study evaluating treatment of *C. acnes* infection after Cotrel-Dubousset instrumentation, Bemer et al. conducted a retrospective study investigating various treatment regimens including complete or partial implant removal, implant replacement and maintenance of implants with irrigation and debridement, both with and without antibiotics. Patients who underwent partial removal with antibiotic monotherapy or absence of antibiotic therapy were more likely to develop a secondary infection. Ultimately, wide variation in treatment regimens prevented more mean-

ingful analysis of the results, though the authors concluded that complete removal of implants should be performed when possible and antibiotics should be tailored to the sensitivities of the specific organism and given for a duration of three to six months or less than three months when following total implant removal [19]. In another large case series of surgical site infection (SSI) after spine surgery, Maruo and Berven listed *C. acnes* infection as an independent risk factor for treatment failure ($p = 0.042$) [4]. Though they did not comment on the specific treatment strategies utilized for patients with *C. acnes* SSI, they note that 7 of 12 patients (58%) with late infection treated with implant retention and antibiotics required subsequent implant removal.

Due to the variation in treatment strategies for *Propionibacterium acnes* infections of the spine and the lack of prospective trials evaluating optimal antibiotic regimen, the optimal treatment of spinal infections with *C. acnes* is indeterminate. However, given reports of numerous successful treatment strategies in the literature, complete removal of implants when applicable followed by an extended course of parenteral antibiotics results in overall high cure rates for *C. acnes* infections of the spine.

3.2. TREATMENT: ANTIBIOTICS

Authors: John Koerner, Katherine Belden

QUESTION 1: Is there a role for oral antibiotics in the treatment of early postoperative spine infections?

RECOMMENDATION: There may be a role for highly bioavailable oral antibiotics in the treatment of early postoperative spine infection in select circumstances.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Broad-spectrum intravenous (IV) antibiotics may be indicated prior to identification of the infecting organism in patients with early postoperative infections while waiting for surgical intervention, or for patients who are medically unstable and cannot undergo surgery [1]. Other than the latter cases, there is no role for oral antibiotics alone in the treatment of patients with acute postoperative spine infections. Patients with established postoperative infections of the spine require surgical intervention.

The administration of antibiotics may potentially adversely affect the outcome of treatment of these patients by interfering with isolation of the infecting organism. Antibiotic therapy should be withheld in patients with suspected spine infection, as the yield for biopsy to isolate the infecting organism is reduced when the antibiotic is administered. In a study by Cornett et al., the yield for biopsy culture dropped from 80% for those who did not receive antibiotics to 48% for those who did [1]. Another study of 87 patients, however, demonstrated that the yield for biopsy of spondylodiscitis did not significantly decrease with prior treatment of antibiotics [2]. Despite this, it is still recommended that antibiotics be withheld when possible. If antibiotics are to be administered, biopsy is still indi-

cated to isolate the infecting organism and allow for optimal treatment of the patient.

In a large case series of 1,980 patients, 74 infections were diagnosed [3]. The treatment algorithm consisted of six weeks of IV antibiotics if the patient was not fused. If the patient was fused, *Staphylococcus aureus* and gram-negative infections were treated with six weeks of IV antibiotics followed by six weeks of oral antibiotics with implant removal. In patients with propionibacteria and coagulase-negative *Staphylococcus*, four weeks of oral antibiotics were given. Oral antibiotics were not recommended as an initial treatment. Other studies have demonstrated the benefit of oral antibiotics as suppression therapy after treatment with surgical debridement and a course of IV antibiotics [4,5].

Multiple other studies have demonstrated the benefit of surgical debridement and IV antibiotics for infection [6]. In a consecutive case series of 2,391 patients, 46 cases of wound infection were identified and all treated with surgical debridement [7]. One series of 111 patients identified eight patients with postoperative infections after posterior lumbar interbody fusion [8]. All were treated with irrigation and debridement followed by four to six weeks of intravenous antibiotics followed by another six to nine weeks of oral antibiotics.

Multiple case series and expert opinion studies recommend avoiding oral antibiotics in suspected postoperative infection until culture samples are taken for better diagnosis and accurate treatment of these patients [9]. The majority of patients with established postoperative infection require surgical debridement.

QUESTION 2: Is there a role for the use of oral antibiotic in treatment of acute and chronic spinal infections?

RECOMMENDATION: There may be a role for highly bioavailable oral antibiotics in the treatment of acute and chronic spine infection in select circumstances.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Vertebral osteomyelitis

In vertebral osteomyelitis (spondylodiscitis) without an implant, experts recommend a treatment duration of 6 to 12 weeks [1]. However, a retrospective study over 10 years by Roblot et al. found no difference in relapse rate comparing 6 and 12 weeks of treatment [2]. An open label, non-inferiority, randomized, controlled trial by Bernard et al. firstly showed that 6 weeks was not inferior to 12 weeks. In both groups, intravenous treatment was only given for a median time of 14 to 15 days and was followed by an oral fluoroquinolone and rifampin combination or aminopenicillin (both regimens with high oral bioavailability) [3]. The authors could not see a difference in the proportion of treatment failure between patients given intravenous treatment for more than one week and those for less than one week.

Postsurgical infection with an implant

There are many studies in this field regarding optimal treatment duration and agents in spinal implant-associated infections, but they are all retrospective with low levels of evidence. There are no up-to-date prospective and/or randomized studies published investigating the optimal duration of antibiotic treatment and the role of oral antibiotics in implant-associated spinal infections.

Most studies demonstrated successful treatment of spinal implant-associated infections with a total duration of six weeks [4–6]. If implants are not removed, reported durations of treatment are up to 12 weeks with intravenous treatment for 6 weeks, followed by oral antibiotic treatment for another 6 weeks [7,8].

Yet, regarding duration of intravenous treatment, there are no clear recommendations. Some studies treat intravenously for a prolonged time for up to four [8–10] or six weeks [4,11–13]. But there are also retrospective studies in which intravenous treatment was given for two weeks or less followed by oral antibiotics with good oral bioavailability [14]. Billieres et al. did a multivariate analysis on risk factors for relapse of infection and did not find an association with duration of total or intravenous antibiotic treatment [14]. Another study by Kowalsky et al. also concluded that duration of

intravenous treatment is no risk factor for neither acute nor chronic infections [15].

Author: Susana Núñez-Pereira

QUESTION 3: Is there a role for chronic antibiotic suppression after treating patients with retained infected spinal hardware?

RECOMMENDATION: The use of chronic antibiotic suppression (CAS) has not been clearly investigated until now. However, it can be an option for patients whose implants cannot be removed or who refuse further surgeries because of comorbidities.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 93%, Disagree: 0%, Abstain: 7% (Super Majority, Strong Consensus)

RATIONALE

Only one study has compared patients receiving CAS [1]. They found that 5 out of 22 patients with CAS had treatment failure, compared with 5 out of 6 in the control group. The definition they used for treatment failure was described as the need for an unanticipated debridement or a clinician's decision to give a second course of antibiotics. Suppressive antibiotics were given for a median time of 303 days (IQR 147 to 672) to patients with early onset infection and 410 days (IQR 61 to 667) to patients with late onset infection. Data on treatment failure was reported only for early onset infection patients. It could be argued that patients already under CAS would not have been eligible for a second course of antibiotic treatment and this could partly increase the rates of treatment failure on the group without CAS, biasing the study results.

Other studies reporting on antibiotic treatments show large variations in the duration of treatment. Miyazaki et al. reported a mean duration of oral treatment of 336 days, ranging from 89 to 1,673 days [2]. Their study focused on multi-resistant surgical site infection treated with implant retention. Maruo et al. reported an average duration of antibiotic treatment of 255.8 days with a standard deviation of 283.4 days [3]. All these reports show a huge variation in the length of antibiotic treatment, with a select group of patients in each study receiving CAS. Decision for prolonged CAS was made at the clinician's discretion and based on the patient's symptoms, so there is no particular setting in which it would be possible to offer a sound recommendation. Besides the mentioned paper by Kowalski, there are no reports comparing CAS with other treatment regimes.

QUESTION 4: Is there a role for combination antibiotics (i.e., dual or triple) in treating patients with surgical site infection (SSI) following spinal surgery?

RECOMMENDATION: There is insufficient evidence to recommend the routine use of combination antibiotics in the setting of postoperative spine infections. However, there may be a role for combination antibiotics in certain circumstances related to specific pathogens.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 87%, Disagree: 13%, Abstain: 0% (Super Majority, Strong Consensus)

RATIONALE

The incidence of postoperative spine infection has been reported as between 0.7 and 16%, with higher rates noted in procedures with hardware implantation [1,2]. The most common organisms isolated are *Staphylococcus aureus*, *Staphylococcus epidermidis*, methicillin-resistant *S. aureus* and *Enterococcus*. Up to 20 to 30% of infections are noted to be poly-microbial [3,4].

Antibiotic treatment is directed at the isolated micro-organism/s and usually only a single anti-microbial agent is used. There are a few reports of dual antibiotic therapy with rifampin, the most common additive agent [3,5]. Rifampin is chosen due to its ability to penetrate biofilms associated with implant-related infections [6]. Evidence from a mouse model has shown that the addition of rifampin to vancomycin led to an increase in bacterial death, but no change in the final outcome from the SSI [7]. There are no clinical studies comparing the use of single to multi-agent antibiotic therapy for postoperative spine infections.

Author: Yvonne Achermann

QUESTION 5: How long should antibiotics be administered after surgical debridement for an acute postsurgical spinal infection?

RECOMMENDATION: For vertebral osteomyelitis: Initial intravenous treatment for one to two weeks, followed by an oral treatment of four to five weeks to reach a total treatment duration of six weeks.

For deep surgical site infections: There is limited knowledge about the ideal duration of antibiotic treatment and which intravenous and/or oral agents should be given. As extrapolated from studies in periprosthetic joint infections (PJIs) and retrospective studies in spine infections, 12 weeks of antibiotic treatment can be recommended in cases with early infection and implant retention, six weeks if the implant is removed and prolonged suppressive treatment in delayed infections without removal of the implant.

LEVEL OF EVIDENCE: Moderate for vertebral osteomyelitis. Limited for surgical site infections after spine surgery

DELEGATE VOTE: Agree: 80%, Disagree: 13%, Abstain: 7% (Super Majority, Strong Consensus)

RATIONALE

Vertebral Osteomyelitis

In vertebral osteomyelitis (spondylodiscitis) without an implant, experts recommend a treatment duration of 6 to 12 weeks [1]. However, a retrospective study over 10 years by Roblot et al. [2] found no difference in relapse rate between 6 and 12 weeks of treatment [2]. An open label, non-inferiority, randomized, controlled trial by Bernard et al. first showed that 6 weeks was not inferior to 12 weeks. In both groups, intravenous treatment was only given for a median time of 14 to 15 days followed by an oral fluoroquinolone and rifampin combination or aminopenicillin (both regimens with high oral bioavailability) [3]. The authors could not see a difference in the proportion of treatment failure between patients given intravenous treatment for more than one week and those for less than one week.

Postsurgical infection with an implant

There are many studies in this field regarding optimal treatment duration and agents in spinal implant-associated infections, but they are all retrospective with low levels of evidence. There are no up-to-date prospective and/or randomized studies published investigating the optimal duration of antibiotic treatment and the role of oral antibiotics in implant-associated spinal infections.

Most studies demonstrated successful treatment of spinal implant-associated infections with a total duration of six weeks [4–6]. If implants are not removed, reported durations of treatment are up to 12 weeks with intravenous treatment for six weeks, followed by oral antibiotic treatment for another six weeks [7,8].

Yet, regarding duration of intravenous treatment, there are no clear recommendations. Some studies treat intravenously for a prolonged time for up to four [8–10] or six weeks [4,11–13]. But there are also retrospective studies in which intravenous treatment was given for two weeks or less followed by oral antibiotics with good oral bioavailability [14]. Billieres et al. did a multivariate analysis on risk factors for relapse of infection and did not find an association with duration of total or intravenous antibiotic treatment [14]. Another study by Kowalsky et al. also concluded that duration of intravenous treatment is not a risk factor for acute chronic infections [15].

QUESTION 6: How long should antibiotics be continued when spinal wounds are left to heal by secondary intention?

RECOMMENDATION: Only standard perioperative antibiotic prophylaxis is recommended.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 93%, Disagree: 0%, Abstain: 7% (Super Majority, Strong Consensus)

RATIONALE

Following spine surgery, surgical wounds are normally closed via primary intention where all tissue is fastened closed with sutures, staples, glue or some other form of closure material. In rare cases, however, wounds are left to close naturally via secondary intention. Normally, this is done in cases where the risk of persistence of infection is high or when a large gap in soft tissue exists as a result of tissue loss.

Antibiotic prophylaxis has been shown to be useful in preventing infection following spine surgery. However, no specific agent or schedule has been identified as superior over any other [1].

In a randomized, blinded, controlled study, Gupta et al. found that topical antibiotics, specifically sucralfate, increased wound healing in patients at four weeks following hemorrhoidectomy left to heal via secondary intention when compared to placebo (78% compared to 52%) [2]. In contrast, Doung et al. found that the use of trimethoprim-sulfamethoxazole in pediatric skin abscess treatment compared to placebo did not significantly affect the recurrence of new lesions in the long term [3].

A systematic review by Norman et al. found that no robust evidence exists on the relative effectiveness of any antibiotic preparation in cases where surgical wounds have been left to heal by secondary intention [4]. There is no high-level evidence directly related to spine surgery for this topic. In general, if there is hardware present, patients often should receive at least six weeks of intravenous antibiotics and continued suppressive antibiotics until the wound heals.

QUESTION 7: What is the optimal duration of antibiotic treatment following spine infection in patients within whom hardware is retained? Is the antibiotic treatment different for those with spine infection without hardware?

RECOMMENDATION: There are no case-control studies allowing for an evidence-based recommendation on the optimal length of antibiotic treatment following spine infections in the presence of retained hardware. The most commonly implemented antibiotic regime is three months. However, duration of treatment was highly variable among all studies. Patients with non-instrumented surgeries did well with a shorter course of antibiotics.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 93%, Disagree: 7%, Abstain: 0% (Super Majority, Strong Consensus)

RATIONALE

After searching PubMed, CINAHL and Embase (with MeSH terms "surgical site infection," "spine" and "antibiotic") and reviewing 381 abstracts, a final 14 studies included treatment of spinal surgical site infection (SSI) with retained implants (including data on antibiotic treatment regimens) [1–14]. There were no studies analyzing or comparing different antibiotic regimes. Most of these studies were retrospective in nature, however one study was a prospective observational study. There were no studies comparing different antibiotic treatment regimens. There was also a wide variation in the duration of treatment among the studies ranging from 42 to 597 days in 1 study, and ranging between 89 and 1,673 days in a separate study [9,11]. These variations were usually related to treatment failure or poor control of the infection. Of 14 studies, 7 reported mean antibiotic treatments of 12 weeks or 3 months [3–6,10,13,14]. All but three studies reported on time of intravenous (IV) and oral antibiotics. The most reported mean time for IV antibiotic administration was an average of four to eight weeks in eight studies. One study reported on 81 SSIs, of which 39 were treated with suppressive antimicrobial therapy [2]. At final two-year follow-up, seven patients were still under antibiotic treatment.

Three studies reported data on patients with early and late infection [2,5,10]. Also, there were significant variations regarding the onset of infection. Some studies only reported ranges and gave no mean or median values. Of the nine studies with available mean data, mean time to onset of infection was 103.2 days. Removing an outlier with 778 days for late infection, mean time to onset of infection was 18.98 days (range of mean values was 2.9 to 54)

There was only one retrospective study analyzing the antibiotic treatment regimen in a series of 74 patients, all with implant removal (IR) [15]. Patients had a median duration of IV antibiotics of four weeks and an additional five weeks of oral antibiotic treatment. There were no comparative studies regarding different antibiotic regimen.

Regarding IR, there were two very different settings in which implants had to be removed. Of 729 SSI cases recorded in the 15 studies, implants were removed in 195 patients (26.74%). In 114 cases (15.6%), IR was performed as part of SSI treatment during the first debridement procedure. In the remaining 81 cases (11.11%), IR was performed because of treatment failure after several debridement procedures. The fact that IR can be split into two differentiated groups makes it more difficult to compare treatment regimes. Usually, when IR was performed as the initial treatment, antibiotic regimens tended to be shorter [15]. On the other hand, when IR was performed because of treatment failure, antibiotic treatments were longer.

With regards to non-instrumented spine surgeries, Maruo et al. compared 59 non-instrumented infections with 166 instrumented cases [8]. They reported longer antibiotic treatment for instrumented cases (mean 40 days IV vs. 25.4 in non-instrumented and mean 255 days oral vs. 42). Only 10% of the non-instrumented cases needed more than one debridement compared to 28% for instrumented spine procedures. Of the non-instrumented spine surgeries, 20% were successfully treated without surgical debridement compared to only 6% of instrumented spine procedures.

QUESTION 8: What tests should be used to monitor response to antibiotic treatment in patients with spine infection?

RECOMMENDATION: Serum C-reactive protein (CRP) levels are closely related to clinical response in spine infections and are therefore the preferred marker in monitoring the therapeutic course.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 93%, Disagree: 7%, Abstain: 0% (Super Majority, Strong Consensus)

RATIONALE

In two large retrospective studies including 363 patients, criteria for discontinuation of treatment included CRP normalization in addition to resolution of clinical symptoms [1,2]. A weekly decrease of CRP by 50% has been suggested as a therapeutic response in the retrospective study population [3].

Lack of normalization of serum CRP levels is a predictor of treatment failure and warrants additional evaluation, as demonstrated both by a retrospective cohort including 79 patients and a prospective study including 21 patients followed for postsurgical wound infections of the spine [4–5].

Moreover, in a retrospective analysis of 61 patients treated for bacterial spondylodiscitis, the only predictor for de-escalating intravenous therapy to highly bioavailable oral agents was a CRP decrease by week 2 of therapy [6].

QUESTION 9: Which is the best alternative antimicrobial therapy for fluoroquinolone-resistant gram-negative acute post-surgical infection in spinal surgery?

RECOMMENDATION: The choice of antimicrobial therapy should be based on the pathogen and the susceptibility profile.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 93%, Disagree: 7%, Abstain: 0% (Super Majority, Strong Consensus)

RATIONALE

Currently, over 30% of all spinal surgical site infections (SSIs) are secondary to gram-negative bacteria (GNB). Focusing on acute post-surgical infection of spinal surgery, there is no published experience regarding the best therapeutic strategies in case infection by GNB resistant to quinolones. Thus, the treatment criteria used in these cases are the same as those used in the case of fluoroquinolone-resistant GNB periprosthetic join infections (PJIs). The importance of using fluoroquinolones in acute PJIs due to gram-negative bacilli has been demonstrated, but limited antimicrobial agents are available in the case of implant-associated infections caused by fluoroquinolone-resistant GNB [1–3].

The most commonly used antibiotics in the event of fluoroquinolone resistance are β-lactams and carbapenems with or without anti-pseudomonal activity [4]. Grossi et al. described the outcome of 76 GNB-PJIs managed with a curative intent and in their experience, intravenous β-lactams throughout treatment duration (median 90 days) results in an effective alternative to fluoroquinolones [5].

Therapeutic alternatives to β-lactams have been poorly assessed. Cotrimoxazole, which can be switched to oral therapy, has been successfully used in some of these cases [1–6]. Other possible alternatives are the "recovery" of the use of less conventional antibiotics, such as colistin and fosfomycin [7–9]. Colistin shows good spread in bacterial biofilm and a synergistic effect when combined with other antibiotics, especially β-lactams, and has been demonstrated to be effective in vitro against *P. aeruginosa* and enterobacteria [7]. Corvec et al. compared the activities of fosfomycin, tigecycline, colistin and gentamicin (alone and in combination), against a CTX-M15-producing strain of *Escherichia coli* in vitro and in a foreign-body infection model [10]. Fosfomycin was the only single agent, which was able to eradicate *E. coli* biofilms (cure rate, 17% of implanted, infected cages). In combination, colistin plus tigecycline (50%) and fosfomycin plus gentamicin (42%) cured significantly more infected cages than colistin plus gentamicin (33%) or fosfomycin plus tigecycline (25%) ($p < 0.05$). The combination of fosfomycin plus colistin showed the highest cure rate (67%), which was significantly better than that of fosfomycin alone ($p < 0.05$). Therefore, the authors conclude that the combination of fosfomycin plus colistin is a promising treatment option for implant-associated infections caused by fluoroquinolone-resistant GNB, but the effectiveness of this combination should be assessed in vivo.

Other potential therapeutic alternatives are combinations that include tigecycline or rifampin for their demonstrated in vitro synergism with several drugs. Tigecycline has been used for carbapenemase-producing gram-negative PJIs, although bone concentrations of the drug are usually lower than the minimum inhibitory concentrations of these bacteria [11]. Drapeau et al. recently described a literature review of 19 clinical studies on the use of rifampin in treatments for multidrug resistant gram-negative (MDRGN) bacterial infection [12]. Nonetheless, the real clinical benefit of using rifampin-containing therapies for MDRGN bacteria in terms of clinical outcome and survival rates remains to be defined.

The development of new agents (ceftazidime/avibactam, aztreonam/avibactam, cefiderocol, ceftolozane/tazobactam) with activity against MDRGN bacteria will provide important therapeutic options for clinicians, but definitive data showing clinical efficacy is currently lacking [13].

The efficacy of intrawound tobramycin powder in terms of eradicating a known bacterial contamination in an *Escherichia coli*-infected rabbit spinal implantation model was assessed, with the researchers concluding that intrawound tobramycin eliminated *Escherichia coli* surgical site contamination [14].

QUESTION 10: Is there a difference in the efficacy of vancomycin beads versus vancomycin powder for spinal implant infections?

RECOMMENDATION: It is unclear whether there is a difference in the efficacy of vancomycin beads versus vancomycin powder for spinal implants infections.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 93%, Disagree: 0%, Abstain: 7% (Super Majority, Strong Consensus)

RATIONALE

Currently, there are no studies comparing or individually evaluating the efficacy of vancomycin powder and vancomycin beads for the treatment of infections following spinal instrumentation.

3.3. TREATMENT: IMPLANTS

Authors: Pouya Alijanipour, Caroline Granger

QUESTION 1: Should a cage be removed in patients with postoperative spine infection?

RECOMMENDATION: No. The interbody cage can be maintained in the absence of clinical and radiographic signs of loosening or displacement of the cage or compression on neural and vascular structures. However, the cage should be removed if the infection persists despite salvage attempts consisting of irrigation and debridement procedures combined with intravenous antibiotic treatment.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 73%, Disagree: 0%, Abstain: 27% (Super Majority, Strong Consensus)

RATIONALE

The incidence of surgical site infection in the presence of an interbody cage depends on various factors including the type of approach (anterior, posterior or lateral) and whether the cage is stand-alone or associated with posterolateral instrumentation fusion. Series with stand-alone posterior lumbar interbody fusion (PLIF) or anterior lumbar interbody fusion (ALIF) have lower infection rates (up to 3%) compared to those with long constructs in degenerative adult scoliosis (up to 11%) [1]. On the other hand, adding interbody fusion to posterolateral spinal fusion can be a risk factor for infection and a series of posterolateral fusion with interbody fusion reported higher incidence of surgical site infection compared to those without interbody fusion, most probably due to prolonged surgical procedure, increased blood loss and tissue damage associated with interbody fusion (0.3% versus 1.4%) [2].

Spondylodiscitis at the site of an interbody fusion can present with or without signs of superficial wound infection. If superficial infection does not exist, deep infection can be underestimated or ignored initially due to late presentation. In one report, the average time to diagnosis for spondylitis in patients with PLIF was 164.5 days (range 10–410 days) and time to diagnosis longer than three months was the only predictive factor of failure of intravenous antibiotic treatment and need for implant removal [3]. Moreover, the intervertebral disc tissue is a naturally avascular tissue, limiting the efficiency of immune response as well as efficiency of antibiotics for eradication of infection. Delayed treatment of cage infection can be associated with the risk of extension of infection to the neural elements as well as to the vital retroperitoneal organs and major vessels with disastrous consequences [4].

Cage removal is associated with a risk of interbody space collapse, foraminal narrowing, loss of alignment, progression of deformity, loss of fixation, instability and pseudoarthrosis [5]. On the other hand, inappropriate cage retention can establish bacterial colonization and biofilm formation on the surface of the implants, and diminishes the efficacy of antibiotic treatment [6]. Time of presentation (early versus late postoperative infection), chronicity and severity of symptoms are other considerable factors [7,8].

According to the published case series, in most cases of interbody cage infection, the cage can successfully be retained with an initial salvage attempt consisting of irrigation and debridement procedures combined with antibiotic treatment [1,9–15]. Although, there is no agreed definition criteria for failure of salvage treatment, the following conditions have been considered as indication of cage removal: presence of discitis, osteomyelitis, signs of cage loosening, epidural abscess, extension of infection to soft tissues and presence of bone loss [1,4,8]. Most of these criteria are based on the findings of advanced imaging such as computed tomography and magnetic resonance imaging. One study presented 10 cases with uncontrolled infection of interbody cage, all of which were placed via posterior

approaches. In 9 out of 10 cases, solid bone fusion was achieved via an anterior procedure consisting of cage removal and the use of autogenous iliac bone graft to fill the interbody space [16]. An anterior approach for removal of a posteriorly-placed interbody cage prevents complications associated with epidural scar tissue and fibrosis due to the inflammatory response to the original surgery and infection process [16].

QUESTION 2: Is there a length of time of infection beyond which instrumentation should be removed?

RECOMMENDATION: The data suggests that early infection can commonly be treated with implant retention and debridement followed by intravenous (IV) antibiotics and common oral antibiotic treatment. If the patient has achieved spinal fusion, the implants can be safely removed. In the setting of pseudarthrosis, thought should be given to removal of implants to eradicate infection followed by re-instrumentation.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

The primary goals of treating postoperative spinal surgical site infections (SSIs) are to eradicate the infection, maintain stability and achieve fusion (when warranted). While the decision to retain existing instrumentation in the setting of an acute infection may be necessary for maintaining stability or promoting fusion, this may jeopardize the surgeon's ability to completely eradicate the SSI. The preponderance of available evidence suggests the ability to both retain hardware and successfully eradicate the infection depends on the acuity of the presentation, with early diagnoses of SSI (within 30 to 90 days after index procedure) having higher rates of successful retention after debridement and IV antibiotics, while deep infections over one year commonly require removal.

Several studies have demonstrated successful eradication of infection with debridement and hardware retention for early-onset SSI. Patel et al. reviewed surgical debridement and retention of instrumentation in 17 patients with SSI after spinal arthrodesis ranging from 1 to 6 weeks after the index procedure, noting eradication of infection in all patients and successful fusion in 15 of 17 (88.2%) [1]. Sierra-Hoffman et al. reported successful instrumentation retention with early onset (< 30 days) SSIs with debridement and long-term antibiotics alone, noting eradication of infection in 17 out of 19 (89.5%) patients. However, six of the seven late infections (> 30 days) ultimately required instrumentation removal for eradication of the infection [2].

Pull ter Gunne et al. noted that their management of SSI involved aggressive debridement (89.3%) with hardware retention (if stable) and revision of hardware (if unstable), followed by an average of 40 days of antibiotics. With this protocol, 76% of their deep infections were eradicated with a single debridement, although no comment was made about the chronicity of the SSI prior to reoperation [3]. Kowalski et al. reported on 30 acute SSIs (< 30 days) with 80% successfully retaining implants with surgical debridement and IV antibiotics followed by oral suppressive antibiotics [4]. Tominaga et al. reviewed risk factors for unavoidable

removal of instrumentation after SSI < 90 days, finding that 12 of 16 cases successfully retained implants after debridement and IV antibiotics, but noted that 3 of 4 failures grew methicillin-resistant *Staphylococcus aureus* (MRSA) on operative cultures, compared with only 1 of 12 successfully-treated cases diagnosed with MRSA [5]. Nunez-Pereira et al. reported 43 patients with acute SSI after posterior spinal fusion requiring debridement and IV antibiotics for at least 8 weeks, finding 90.7% survival (survival to follow-up timepoint with avoidance of implant removal) at 6 months, 85.4% at 12 months, and 73.2% out to 4 years [6]. Multivariate analysis revealed a significant risk of treatment failure in patients who developed sepsis (hazard ratio 12.5 [95% confidence interval 2.6 to 59.9]; $p < 0.001$) or who had more than three fused segments (hazard ratio 4.5 [95% confidence interval 1.25 to 24.05]; $p = 0.03$) [1].

Accurately predicting the number of required debridements to eradicate the SSI can be challenging. Thalgott et al. identified that initial debridement culture results and the patient's comorbidities, including systemic disease, immunocompromise and malnourishment, are prognostic for the number of debridements required. Healthy patients with less virulent bacteria commonly required a single debridement, while immunocompromised hosts, multiple and/or more virulent organisms, and polymicrobial infections often require multiple debridements [7]. DiPaola et al. evaluated risk factors predicting multiple debridements, identifying MRSA and distant site infection as the strongest predictors, and diabetes mellitis, the presence of instrumentation, use of allograft and posterior lumbar spine location also displaying significant associations [8].

Conversely, delayed diagnoses of SSI commonly require implant removal for successful infection eradication. Hedequist et al. found all 26 cases with SSIs presenting greater than 3 months postoperatively required implant removal to definitively clear the infection [9]. Similarly, Kowalski et al. reported 7 out of 13 late diagnoses of SSI (> 30 days) failed debridement and initial implant retention, requiring secondary surgery for implant removal [4]. Tsubouchi et al. noted that although 29 out of 43 patients successfully retained spinal implants for SSI < 30 days postoperatively, only 4 of 12 patients diagnosed later than 30 days and 0 of 4 patients diagnosed later than 90 days successfully retained implants [10]. Garg et al. reported on 42 patients with deep infection more than 1 year postoperatively after spinal fusion, noting that 41 required implant removal and retention attempted in 1 patient failed. Additionally, 27 of the 42 patients showed *C. acnes* on intraoperative cultures [11].

Ho et al. reviewed their experience with pediatric SSI after instrumented fusion for scoliosis, noting that 43 out of 53 (81%) patients had retained implants at their first irrigation and debridement. They found a significant increase in secondary debridement required with implant retention (47%) in comparison to implant removal at the first irrigation and debridement (20%). However, implant removal was associated with a 10-degree or greater curve progression in 60% of patients [12]. Balancing the need for spinal stability and prevention of deformity progression or pseudarthrosis against a more complete eradication of infection remains a case-by-case decision guided by surgeon experience.

Mok et al. reviewed the functional impact of infection after posterior spinal fusion with 12 early (< 90 days) and 4 late (> 90 days) SSIs undergoing debridement with retention of instrumentation, and reported no significant difference in long-term SF-36 outcomes compared with non-infected controls at an average follow-up of 56.7 months [13]. Kuhns et al. similarly compared quality of life (QOL) scores between infected posterior cervical fusions requiring reoperation to noninfected matched controls. While the total projected costs were increased ($21,778 vs. $9,159) and 6-month QOLs were significantly lower for the infected cohort, no significant differences were found in QOL outcomes at the 12-month follow-up [14].

Recent literature has questioned the significance of time-based decision-making for implant removal following SSI and instead has turned to advanced imaging to understand the causes of implant retention failures. Kanavama et al. evaluated preoperative magnetic resonance imaging (MRIs) in SSIs, noting that once vertebral osteomyelitis and/or intervertebral abscess were evident in MR images, all the hardware should be removed [15]. Six of seven patients without osteomyelitis or intervertebral abscess successfully retained implants, while 9 of 13 patients with osteomyelitis or intervertebral abscess ultimately required implant removal and three of four patients who retained implants resulted in loss of fixation stability [15].

QUESTION 3: Should bone graft be removed in patients with postoperative spine infection? If yes, should a distinction be made between allograft and autograft?

RECOMMENDATION: Bone graft need not be routinely removed following irrigation and debridement, especially if partially incorporated. However, loose or purulent graft should be considered for removal. Retained allograft may increase the risk for requiring repeat debridement compared to autograft.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 87%, Disagree: 0%, Abstain: 13% (Super Majority, Strong Consensus)

RATIONALE

No literature could be found that directly stratified patients who had bone graft retained versus removed. Weinstein et al. studied 46 postoperative infections in 2,391 patents [1]. In their regimen, bone graft material that appeared viable was left in place and instrumentation was retained as well. After six weeks of antibiotics, all of the wounds healed. Massie et al. similarly reported that bone graft may be retained and rarely is it necessary to remove all bone graft [2]. Ahmed et al. also showed in their retrospective review that debridement and antibiotics with implant and bone graft retention (allograft and autograft) can result in complete eradication of infection [3].

Nonetheless, bone graft loosened by irrigation may be removed. It seems rational that unincorporated bone graft and loose, dead bone serves as a continued nidus for infection and as such should be removed [4]. Multiple authors thus recommend thorough irrigation and debridement with removal of nonviable, purulent and loose graft material. However, this appears largely based upon intuition and not strict evidence.

There is limited evidence that perhaps autograft is better tolerated in the setting of an infection. Dipola et al. created a predictive model to differentiate patients requiring one versus multiple debridements [5]. The use of bone graft rather than autograft was shown to be predictive of requiring multiple debridements. Perhaps, therefore, closer attention ought to be given to the viability and infection burden in patients with allograft. However, no specific recommendations can be given and this should be considered on a case-by-case basis, with considerations of host status, infectious organism and infection burden.

QUESTION 4: What are the indications for implant retention or removal of hardware in spinal infections?

RECOMMENDATION: In early or acute infections, debridement with retention of the implant might be possible and should always be favored, as removal of the implant carries a great risk for non-fusion despite the risk of chronic low-grade infections with possible implant loosening. In late infections, removal is recommended if feasible.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 87%, Disagree: 7%, Abstain: 6% (Super Majority, Strong Consensus)

RATIONALE

Similar to periprosthetic joint infections (PJI), several authors recommend that in early spinal implant-associated infections (within one month after surgical treatment or symptom duration less than three weeks), a debridement with retention of the implant constitutes a sufficient treatment strategy [1–5]. However, their recommendation is based on a retrospective, small case series of patients. There are also reports describing continuous irrigation in early infections [6,7], but no controlled studies with non-continuous irrigation are published.

In chronic infections, which are often caused by low-grade pathogens, such as coagulase-negative staphylococci or *Cutibacterium acnes*, removal of implants is regarded as the treatment of

choice [3,8–10]. Infections with low-grade pathogens often present in a delayed fashion so that the implant-associated biofilm is mature and bacteria in the biofilm cannot be killed by antibiotics only or debridement with retention of the implant. In addition, patients with chronic infections often present with pseudarthrosis [11]. Hedequist et al. retrospectively reported on 26 chronic infections in which curing was only achieved after removal of the implants with prior unsuccessful treatment attempts with implant retention [12]. In six patients, hardware reimplantation was needed due to progression of the underlying deformity (curve progression). Implant removal carries the risk of disc collapse, lack of fusion, loss of normal lordosis and pseudarthrosis [3,13], which have to be considered.

There are no recommendations as to whether only the dorsal instrumentation or the interdiscal cage should be removed as well for successful treatment. In addition, no prospective clinical trials comparing removal versus retention of the implant in chronic infections exist. Lall et al. nicely summarized treatment regimens of deep wound infections after spinal instrumentation [14].

QUESTION 5: Is there a role for one-stage exchange of hardware in the presence of spinal infections?

RECOMMENDATION: There is insufficient data on one-stage exchange of hardware in the presence of spine infection.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Evidence supports debridement and implant retention in early implant-associated infections. In delayed implant-associated spine infections, evidence favors hardware removal followed by a course of antibiotics. Even if solid fusion is present, significant loss of correction can occur, posing the question of whether one-stage exchange of hardware would be adequate [1]. It is established that placing spinal instrumentation into an infected spine is safe when necessary for spinal stability and eradication infection, with low recurrence and reoperation rates [2]. Data on hardware one-stage exchange in deep infections with instrumentation is lacking.

Infection following instrumented spinal fusion can result in significant morbidity to the patient, resulting in prolonged hospitalization, chronic pain and need for revision surgery. In addition to the morbidity, the economic impact of this type of infection to the healthcare system and patient cannot be overstated. Several risk factors associated with the development of surgical site infection (SSI) following instrumented spinal fusion have been identified [2–4]. Management of superficial infection typically consists of oral or intravenous (IV) antibiotics, with surgical intervention reserved for failure of medical management, symptomatic deep infections or draining wounds with soft tissue compromise. Treatment of deep infections surgically is complicated by the presence of spinal instrumentation. Eradication of infection is the primary goal of surgery, however premature removal of instrumentation can result in pain, pseudoarthrosis and deformity [5–7].

Several series have been published illustrating successful treatment of deep wound infection with irrigation debridement and retention of original instrumentation [8–14]. Picada et al. published on a series of 26 patients with infection following instrumented spinal procedures, with 24 (92.3%) successfully treated with surgical debridement, intravenous antibiotics, nutrition optimization and primary or delayed secondary closure [13].

Kowalski et al. retrospectively reviewed the management of 81 patients with infections following spinal instrumentation. The

cohorts were defined by early and late onset infection [9]. Of the patients with early onset infection, 28 of 30 were treated with irrigated debridement and retention of hardware with predicted probability of treatment success at two years being 71%, while patients with late onset infections required removal of hardware to achieve an 84% probability of treatment success at two years. Maruo et al. retrospectively reviewed a series of 225 consecutive patients with SSIs following spinal surgery [10]. Of those, 126 or 76% were successfully treated with surgical debridement, IV antibiotic therapy and retention of hardware. Failure of this treatment strategy was associated with late infection, long constructs with pelvic fixation, *Propionibacterium acnes* speciation and poly-microbial infection.

Nunez-Pereira et al. published on a series of 43 consecutive patients with SSI treated with surgical debridement and targeted antibiotic therapy with retention of original instrumentation [11]. At a 26-month follow-up, 10 patients (23.3%) failed, requiring removal of hardware, or died. Multivariate analysis found treatment failure associated with sepsis and long constructs (> three levels fused). Tominaga et al. published a retrospective series of 16 consecutive patients who developed SSI following spine instrumentation over an eight-year span [15]. Twelve of the 16 cases (75%) were successfully treated with retention of hardware, with failure associated with long instrumented constructs, previous spinal surgery, low preoperative hemoglobin, high preoperative creatinine and methicillin-resistant *Staphylococcus aureus* (MRSA) speciation. DiPaola et al. developed a predictive model determining the need for single versus multiple irrigation and debridement procedures to successfully eradicate postsurgical spinal infection [8]. The authors identified MRSA-positive cultures, bacteremia, non-autogenous bone graft and diabetics as predictive for requiring multiple debridement procedures. Vacuum-assisted closure (VAC) can be used to help facilitate wound healing following irrigation and debridement with hardware retention for spinal infection [16].

There are several studies illustrating the successful management of SSI following spinal instrumentation with surgical debridement, IV antibiotic therapy and primary or delayed secondary closure. Factors consistently associated with treatment failure included late infection, long constructs with pelvic fixation, *C. acnes*/MRSA speciation and bacteremia. Patients with these characteristics should likely have removal of hardware in addition to surgical debridement. Multiple debridement procedures may be required to successfully treat the infection, which can be assisted by the use of a wound VAC.

3.4. TREATMENT: WOUND CARE

Authors: Carles Pigrau, Gregory Schroeder

QUESTION 1: Should infected wounds undergo primary closure or a two-stage closure?

RECOMMENDATION: The current recommended practice for spine wounds remains primary closure in the majority of postoperative infections. However, there may be circumstances when primary closure of the wound may not be possible or preferred. This may include patients with grossly contaminated traumatic wounds, patients with persistent wound drainage when attempts to address drainage have failed or patients with severe soft tissue loss when primary closure is not possible.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 93%, Disagree: 0%, Abstain: 7% (Super Majority, Strong Consensus)

RATIONALE

Following surgery, wounds are typically closed in a primary fashion. Alternative methods of wound closure include secondary closure and delayed primary closure. Secondary closure is when wounds are left to close naturally on their own. Delayed primary closure (DPC), a combination of secondary and primary closure, is when a wound is cleaned and left open until infection is controlled, followed by surgical closure of the wound. Delayed primary closure is only used on occasion, typically involving contaminated traumatic injuries.

In their prospective randomized study, Singh et al. found that patients undergoing delayed primary closure of contaminated abdominal wounds related to hollow viscus perforation had lower infection rates (17.5%) and shorter hospital stays (18.1 days) when compared to patients undergoing primary closure (42.5% infection and 20.7 days) [1]. Chiang et al. found a similar result for treatment of perforated appendicitis. Patients randomized to primary closure had an infection rate of 38.9% and an 8.4-day length of stay, while patients randomized to delayed primary closure had an infection rate of 2.9% and a 6.3-day length of stay [2].

DPC has also been shown to result in no long-term issues and not be associated with a higher incidence of complications in pediatric liver transplant recipients [3]. Orthopaedic surgeons are familiar with DPC in the context of fasciotomy wounds in patients with compartment syndrome when delayed primary closure is utilized [4,5].

There are, however, no high-level studies related to the role of DPC in spine surgery. In the absence of concrete evidence, and in borrowing from general surgery and other fields of orthopaedics, we feel that primary closure of a wound is the most preferred method of dealing with wound issues in spine patients. However, there may be circumstances when primary closure of the wound may not be possible or preferred. This may include patients with grossly contaminated traumatic wounds, patients with persistent wound drainage when attempts to address drainage have failed and in patients with severe soft tissue loss when primary closure is not possible.

Author: Wesley Bronson

QUESTION 2: What is the indication for muscle advancement flaps in patients with spinal infections?

RECOMMENDATION: Muscle advancement flaps are useful to help close wounds with exposed hardware as well as those which fail local treatment/vacuum-assisted closure (VAC) therapy and to help improve infection eradication.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 93%, Disagree: 0%, Abstain: 7% (Super Majority, Strong Consensus)

RATIONALE

Multiple risk factors exist for wound complications following spinal surgery, including diabetes, chronic obstructive pulmonary disease, resection of neoplasm with excision of significant soft tissue and prior radiation. Additionally, infection is often complicated by loss of soft tissue and poor tissue viability, which leads to an inability to close the wound overall, resulting in exposed hardware [1,2].

Even if the wound is able to be closed primarily or following VAC therapy, it is important to recognize that the same factors that led to the infection and wound breakdown in the first place still exist [3]. To that end, local or vascularized muscle flaps provide multiple advantages over simple wound closure or delayed primary closure. Muscle flaps have been shown to increase blood flow and oxygen delivery, and decrease bacterial load [4–6].

It seems rational that wounds that are completely unable to be closed due to large soft tissue defects with exposed hardware or wounds that fail to close following VAC therapy are reasonable indications for flap coverage. But, the absolute indication for flap coverage following wound debridement in an otherwise closeable wound remains unclear. Multiple authors argue that it remains a reasonable option versus irrigation and debridement with immediate or delayed primary closure.

Dumanian et al. reviewed their experience with flap coverage for spinal wounds [7]. Fifteen patients in their group had postoperative wound dehiscence or infection, with 12 patients having exposed hardware. They were treated with either immediate local flap coverage or two to three days of dressing changes followed by flap coverage. Of the surviving 14 patients, 13 had healed wounds at final follow-up, and none required hardware removal. One patient on chronic steroids/immunosuppression had persistent infection treated with chronic suppressive antibiotics.

Chieng et al. performed a systematic review on the use of flaps for management of wound complications [8]. While several case reports and retrospective series present supportive data, the authors note that relying on the data is difficult as no level 1 or level

2 evidence exists. Additionally, there is a lack of comparative studies directly looking at flap coverage versus traditional wound closure techniques.

QUESTION 3: What is the optimal irrigation solution (volume, type and frequency) during clean or infected spinal surgery cases?

RECOMMENDATION:

1. There is insufficient evidence to recommend for or against normal saline irrigation before closure for the purpose of preventing surgical site infection (SSI) in clean spinal surgery.
2. There is insufficient evidence to support recommendations for optimal volume, type and frequency of irrigation to prevent SSI in clean spinal surgery.
3. Consider the use of irrigation with an aqueous povidone-iodine solution before closure for the purpose of preventing SSI in clean spinal surgery.
4. There is insufficient evidence to recommend for or against chlorhexidine and antibiotic solution irrigation of incisional wounds for the purpose of preventing SSI in clean spinal surgery.
5. There is insufficient evidence to recommend a specific solution (volume, type and frequency) for irrigation in infected spinal surgery.

LEVEL OF EVIDENCE:

1. Consensus
2. Limited
3. Moderate
4. Consensus
5. Consensus

DELEGATE VOTE: Agree: 73%, Disagree: 7%, Abstain: 20% (Super Majority, Strong Consensus)

RATIONALE

1: Irrigation versus no irrigation

No randomized controlled trials (RCTs) or observational studies have compared incisional wound irrigation with normal saline versus no irrigation in clean spinal surgery.

One retrospective observational study evaluating 1,831 posterior lumbar interbody fusion (PLIF) procedures demonstrated a significantly higher risk of SSI with no local bone irrigation compared to those with local bone irrigation in multivariate analysis (odds ratio (OR): 5.248, p = 0.001) [1]. Two retrospective observational studies demonstrated no significant association between interbody irrigation with SSI compared with no interbody irrigation in those undergoing PLIF and lumbar microdiscectomy [1,2].

2: Optimal volume, type and frequency of irrigation for clean spinal surgery

No RCT has compared the amount of normal saline for irrigation to prevent SSI in spinal surgery. One observational study including 223 consecutive spinal operations in a single university hospital demonstrated a significant association with prevention of SSI (OR 0.08, 95%, confidence interval (CI) 0.01 to 0.61) with sufficient amount of saline (mean > 2,000 ml per hour compared with < 1,000 ml per hour) in a multivariate analysis [3].

No RCT or observational study has compared the frequency of irrigation to prevent SSI in spinal surgery.

A very low quality of evidence from two observational studies demonstrated a benefit of pulse pressure irrigation compared to bulb syringe irrigation with normal saline [4,5]. One study showed an advantage of decreasing wound contamination rate in PLIF surgical procedures (OR:6.35, p = 0.046) [4]. Another study showed significant decrease of postoperative infection by ten-fold (11% [28/261] vs. 0.7% [2/263], p < 0.001) by using pulsatile irrigation with vancomycin and ceftazidime prophylaxis for posterior spinal fusion surgeries in adolescent idiopathic scoliosis patients [5].

3 and 4: Optimal solution for clean spinal surgery

There is moderate-quality evidence from two RCTs and two observational studies that povidone iodine irrigation has a signifi-

cant benefit in reducing SSI risk in patients with primarily closed surgical incisions when compared to conventional normal saline wound irrigation [6–9]. In one RCT focusing on primary instrumented lumbosacral posterolateral fusion performed by the same surgeon, SSI was significantly lower in those who underwent 0.35% povidone-iodine irrigation compared with normal saline irrigation (0% [0/120] vs. 4.8% [6/124], p = 0.029), with no significant difference in fusion rate, wound healing, improvement of pain score, function score and ambulatory capacity [6].

In another RCT focusing on spinal surgery, SSI was significantly lower in those who underwent 0.35% povidone-iodine irrigation compared with normal saline irrigation (0% [0/208] vs. 3.4% [7/206], p = 0.0072) [7]. In one observational study comparing before and after the application of combination of 0.3% betadine irrigation with intra-wound vancomycin (VCM) powder (1 gm), the incidence of SSI significantly decreased after intervention (1.3% [15/1173] vs. 2.4% [30/1,252], p = 0.042) with a protective effect in multivariate analysis (OR 0.23, 95% CI: 0.06-0.86; p = 0.0287) [8]. In another observational study involving 950 spinal surgeries comparing before and after application of povidone-iodine and hydrogen peroxide solution irrigation, those irrigated with povidone-iodine and hydrogen peroxide solution were less likely to develop SSI compared with pre-intervention period (0% [0/490] vs. 1.5% [7/460]) [9].

No RCT or observational study has compared chlorhexidine or antibiotic solution irrigation to normal saline irrigation to prevent SSI in spinal surgery.

5: Optimal irrigation for infected spinal surgery

No RCT or observational study has compared incisional wound irrigation with no irrigation in infected spinal surgery.

QUESTION 4: Is negative pressure wound therapy (NPWT) effective in the treatment of wounds that are left to heal by secondary intention?

RECOMMENDATION: There is no evidence that NPWT is superior to conventional standard dressing changes in the treatment of wounds that are left to heal by secondary intention.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 60%, Disagree: 20%, Abstain: 20% (Super Majority, Weak Consensus)

RATIONALE

Animal studies have shown that sub-atmospheric pressure improves the local wound environment through both direct and indirect effects. Sub-atmospheric pressure accelerates healing and reduces the time to wound closure and the incidence of wound infections [1,2]. NPWT removes interstitial fluid and improves lymphatic drainage and microvascular blood flow. It increases oxygen and nutrient delivery in the wound, facilitates removal of metabolic byproducts, increases granulation tissue formation and ultimately accelerates wound healing. Moreover, by isolating the wound from the surrounding environment, NPWT may reduce the colonization of the wound by bacteria and avoid superinfections, particularly in areas with high skin contamination rates such as the perineal and lower back spine area.

Predominantly observational studies, but also small trials (low quality of evidence), have suggested that rates of surgical site infection (SSI) may be lower if NPWT is used instead of conventional wound dressings [3]. In a meta-analysis of six randomized control trials including a systematic review, it was observed that the risk of SSI was reduced when NPWT was used (odds ratio 0.56, 95% CI 0.32 to 0.96) in both clean and clean-contaminated procedures. However, results were no longer significant for orthopaedic/trauma surgery [3]. In a Cochrane meta-analysis that compared NPWT with other types of wound dressing for persistently-draining wounds in skin graft patients, in orthopaedic patients undergoing arthroplasty and general/trauma surgery patients it was concluded that there is no evidence for the effectiveness of NPWT on the complete healing of wounds expected to heal by primary intention [4]. An up-to date systematic review in trauma patients concluded that, based on available observational studies, NPWT [5] was safe and showed an efficacy comparable to standard dressings [6]. The primary clinical advantages of NPWT in the trauma population are its ease of application, decreased

number of dressing changes and reduction in the complexity of subsequent reconstructive procedures [7–11].

In a 2013 systematic review of NPWT for spinal wounds, no randomized clinical trials were found that addressed the use of NPWT to treat wound healing or spine SSIs, nor as prophylactic wound treatment to prevent wound breakdown and infection [12]. The duration of NPWT therapy and the number of debridement and irrigation procedures performed before the definitive wound closure operation were variable. After this review, an additional non-comparative study [12] showed the benefits of this therapy among only 6 of 317 infections after surgery for spinal stenosis. An average of 5.1 debridement and irrigation procedures were performed before the definitive wound closure operation. Vacuum-assisted closure dressings were changed at 3-day intervals and the median duration was 15 days (range 9-24).

After the revision published in 2013, only one longitudinal cohort study addressed NWPT use as a prophylactic therapy for spinal wounds. It is a well-designed, retrospective longitudinal study, which includes 160 adult patients with thoraco-lumbar spine deformity undergoing multi-level thoraco-lumbar fusion [13]. A 50% decrease in the incidence of wound dehiscence was observed in the NPWT cohort (46 cases) compared to the non-NPWT cohort (114 patients) and the incidence of postoperative SSI was significantly lower (10.6% vs 14.9%, $p = 0.04$).

In conclusion, prophylactic use of NWPT may significantly reduce wound dehiscence and wound infection after long-segment thoraco-lumbar spine fusion. There is no further evidence addressing the superiority of NWPT therapy compared to standard dressings. NPWT is safe in cases without dural leaks, easy to apply, and it decreases the number of dressing changes and reduces the complexity of wound closure. All these factors favor its use in selected cases.

Prevention

Authors: Raul Barco Laakso, Samuel Antuña

QUESTION 1: What are the optimal prophylactic perioperative antibiotics for patients undergoing total elbow arthroplasty (TEA)?

RECOMMENDATION: Patients undergoing primary TEA should receive antibiotics that cover gram-positive and gram-negative organisms specific to the regionally encountered organisms. Peer-reviewed literature supports that cefazolin should be dosed based on body weight. Patients with methicillin-resistant *Staphylococcus aureus* (*S. aureus*) colonization should receive weight-based glycopeptide, preferably in combination with cefazolin. Patients with a true hypersensitivity reaction or adverse reaction that precludes the use of cefazolin should receive vancomycin or clindamycin.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

A comprehensive literature search of three online databases (PubMed/Medline, Google Scholar and Embase) was performed using the following MeSH search terms: "elbow," "elbow joint," "joint prosthesis," "arthroplasty" and "replacement."

Because of the evolution of TEA techniques, only articles from the last 10 years were selected, published from January 2008 until January 2018. On the basis of the titles and abstracts, two reviewers independently identified potentially relevant articles for review of the full text. The reference lists of the included articles were manually checked to avoid missing relevant articles. When the full text was obtained, the authors independently selected articles. Studies were not blinded for author, affiliation or source.

Inclusion and Exclusion Criteria

The included articles presented original data on patients who had undergone TEA. The diagnoses included the following indications: osteoarthritis, trauma/fracture, post-traumatic osteoarthritis, rheumatoid arthritis, hemophilia and other inflammatory diseases. Studies with a minimum duration of follow-up of two years and a minimum of 10 patients were included. Studies on revision operations were not included. Articles presenting the results of both revision and primary TEA were excluded unless the information for primary TEA could be extracted. Articles presenting the results for interposition arthroplasties, fully-hinged prostheses, hemiarthroplasty or partial resurfacing of the elbow were excluded. Review articles, expert opinions and surgical technique articles were excluded. When possible, studies comparing different groups were analyzed separately. The search was restricted to articles written in English. Some articles that represented institutional historical databases were included only once.

Data Extraction

After the initial assessment for inclusion, two reviewers extracted data from the included articles. The primary goal was to determine the rate of infection after TEA and the pathogen responsible to determine which is potentially the best antibiotic regimen.

The following parameters were recorded when available: numbers of patients and elbows, design of TEA implant, indication for TEA (e.g., primary osteoarthritis, rheumatoid arthritis, fracture, post-traumatic osteoarthritis or other abnormality), whether the prosthesis was linked or unlinked, the rate of infection and the pathogen responsible for the infection (known/unknown, single/multibacterial). When prophylactic antibiotics were reported, they were recorded. No other attempt was made to extract other data regarding other complications.

Data and Statistical Analysis

Different groups were established on the basis of the preoperative regimen and the causative pathogen, when known. The outcome measures were the rate of infection and the distribution according to the pathogen. When sensitivity antibiotic analysis was performed, this information was also analyzed.

Methodological Quality

The two authors assigned the methodological quality of the included studies according to the Center for Evidence-Based Medicine [1].

RESULTS

Articles

After the removal of duplicate articles, our initial search yielded 227 articles from Medline, Embase and Google Scholar. After title and abstract evaluation, a list of 56 articles was created for full review. After full review, 35 studies were deemed suitable for further evaluation and data collection.

Five studies recorded different articles from an institutional database and a national arthroplasty registry, all being level IV evidence. There were no prospective case series or randomized, controlled trials. Two studies were disregarded as they offered duplicate information [2,3]. Data was extracted into a standard worksheet for further analysis.

Infection Rates and Pathogen Assessment

A total of 303 infections were recorded out of 6,681 patients, for a mean infection rate of 5.6%. Of these, 301 were considered by the authors to be a deep infection for an infection rate of 5.2%, with the other two corresponding to superficial infection.

A pathogen was identified in only five studies. It was not specified if the infection was mono- or polybacterial in all reported case

series. Large et al. reported four cases of deep infection. Two were positive for *Staphylococcus aureus*, one for *Staphylococcus epidermidis* (*S. epidermidis*) and one with no growing organism but a clinical diagnosis of infection [4]. Antuña et al. reported on the outcome of semiconstrained TEA after fracture of the distal humeral and observed 3 infections in 16 patients, 2 being positive for *S. epidermidis* and 1 having negative cultures [5].

Peden et al. reported on the outcome for TEA for an ankylosed or fused elbow, reporting 3 infections out of 13 cases. One occurred perioperatively and the other occurred at 2 and 15 years. Two cases were diagnosed with *Staphylococcus coagulase negative methicillin-resistant* and *S. aureus* [6]. Tachihara et al. reported on the outcome for TEA for rheumatoid arthritis and reported on three infections positive for *enterobacter*, *pseudomona* and *S. aureus*. In all of those cases, the infection was considered monobacterial [7].

Curiously, in a clinical series reporting on 20 elbows diagnosed with periprosthetic joint infection, Streubel et al. reported that 6 out of 21 infections were polymicrobial [8]. In that series, the most frequent pathogen was S. Coagulase-negative (13 patients) followed by *S. aureus* (9 patients) and *Corynebacterium* (3 patients). These patients were initially treated with vancomycin in 10 cases, cefazolin in 8, rifampin in 3 and ceftriaxone in 1 case [8]. This information is in accordance with other studies, although there is a risk of a partial duplicate patient population. In a group of 51 patients, Zarkadas et al. found 17 cases of *S. aureus*, 11 of *S. epidermidis*, 1 of *Serratia*, 1 of *Costiridium*, 1 of *Mycobacteria*, 1 of *C. acnes*, 10 multiorganism infections and 8 cases in which no bacteria was actually grown [9].

Although they are obviously universally used, only 4 of the 35 studies specified the use of prophylactic antibiotics. Of these, only 2 mentioned in their methods the type and dose of antibiotic (a first-generation and a second-generation cephalosporin prior to skin incision in both) [10,11]. Kodde et al. reported the use of 1 gm of intravenous cefazolin 30 minutes prior to skin incision and extended the use for 48 postoperative hour [10]. Lami et al. reported the use of systematic prophylactic antibiotic at induction using a second-generation cephalosporin with no further description. No other information regarding the duration of perioperative antibiotic therapy has been found.

Discussion

The available information is poor regarding infection as a complication after elbow replacement. Specific information on the pathogen, the type and dose of prophylactic antibiotic or the surgical prepping solutions used in cases complicated with an infection after elbow replacement are almost universally lacking in the analyzed studies. The reasons for this are unclear, but might be related to wording restrictions and focus on other aspects of research. Moreover, a definition of infection was not reported and different authors could have used different definitions.

Even though only four studies specified the use of prophylactic antibiotics, we assume these are universally used. Based on the scarce information found and our own clinical experience, first-generation cephalosporin seems to be the most widely used antibiotic. Other options could be used, based on allergies, intolerance or concomitant diseases. However, no sound conclusion can be extracted from literature on this regard.

Authors: Pierre Mansat, Bernard Morrey

QUESTION 2: What is the evidence and recommendation for the use of antibiotic-laden bone cement (ALBC) in primary total elbow arthroplasty (TEA) or in revision TEA?

RECOMMENDATION: There is inadequate evidence to support the use of ALBC during primary or revision TEA.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 96%, Disagree: 0%, Abstain: 4% (Unanimous, Strongest Consensus)

RATIONALE

The response to the question regarding the value of ALBC in a primary and revision setting of TEA requires an understanding of several issues:

1. The specific answer to these questions referable to the elbow cannot be directly answered from the available literature addressing the elbow. Very little information exists for the

elbow, regardless of the level of evidence [1].

2. The clinical features of elbow pathology by definition place all TEAs "at risk," including the underlying diagnosis (a systemic inflammatory disorder or failed intervention for a post-traumatic condition). Primary osteoarthritis is not an indication for TEA as it is effectively treated with debridement. TEA for primary arthrosis was only performed in 18 patients over a 20-year period at the Mayo Clinic, representing about a 2% incidence in our institution [2].
3. Even the less common inflammatory etiology is at particular risk due to the virtual universal management with the immunocompromising disease remitting agents.
4. The subcutaneous location of the joint with little or no muscle protection places it at risk for wound healing problems, which has been documented to increase the likelihood of infection [3,4].
5. The subcutaneous nature and the less robust osseous structure of the elbow increases the complication rate of revision for infection, especially compromising triceps function in more than 25% of patients. In other words, the management of infection by surgical means is poorly tolerated at the elbow (level 4 and 5 evidence) [4].
6. The above observations are supported by the documented infection rate of the primary TEA to be around 5% (3) compared to 1–2% associated with primary hip or knee replacement, but similar to the infection rate of the revision procedures on these joints [4,5].
7. Finally, all the higher-quality literature on the subject relates only to knee and hip replacement with the preponderance of data relating to the knee.

Methodology

The question was addressed in the context of the above and the current literature relating to hip and knee surgery, primarily over the last 10 years. A PubMed literature review was conducted exploring level 1 and 2 randomized control trials, meta-analyses and national registry data. As noted above, all such studies relate only to hip and knee replacement. This review prompted a need for more detail in some instances, followed by level 3 and 4 case series and reports being included.

RESULTS

Use of ALBC in the Primary Total Knee Arthroplasty

- Currently, no conclusive evidence exists regarding the efficacy of antibiotic-loaded cement at the knee in uncomplicated, non-risk patients [6–11].
- Currently, based on the highest-level studies, no recommendation can be made regarding the routine use of antibiotic-loaded cement in primary knee arthroplasty.
- The justification is further weakened by poor cost-effectiveness data for primary knee [12,13], yet primary hip replacement may be cost-effective [14].
- As noted above, this recommendation has no bearing on the question at hand, as by definition all primary TEAs occur in an at-risk population.
- Consensus does exist that ALBC should be used in patients with a high risk of infection (Obesity, body mass index > 35, diabetes mellitus, revision total joint arthroplasty, operative time > 150 minutes, rheumatoid arthritis, a prior history of periprosthetic joint infection, organ transplantation and hemophilia) [5,6,15].

Use of ALBC in Hip Replacement Surgery

- Evidence [16–18], and consensus [19,20] is strong indicating that ALBC does statistically lessen the likelihood of infection after a primary hip replacement, independent of the at-risk patient [21–23].
- Evidence also indicates that ALBC decreases the incidence of deep infections at the hip and at the knee [24] and in hemi-replacement of the hip after fracture [25].
- Therefore, should antibiotic-impregnated cement be used:
  - **A. For primary TEA? Yes, based on:**
    1. Strong evidence supporting its use in primary hip replacement
    2. Strong consensus for ALBC in the at-risk patient and the features of the elbow defining it as an at-risk joint

    Confidence: Extrapolated: moderate; subjective: strong. 100%.
  - **B. For revision TEA? Yes, based on:**
    1. Moderate evidence for effectiveness in revision knee and hip surgery [5,26]
    2. Infection rate of revision TEA exceeds hip and knee revision, as well as increased difficulty and complication rates when treating an infected TEA [27]

    Confidence: Strong. 100%.

Additional Questions to Consider

1. **Which antibiotics(s) should be used?**
   - For primary and revision, combination therapy is recommended (total of 2 gm/40 gm monomer).
   - An aminoglycide, either 1 gm/40 gm cement gentamycin or tobramycin (tobramycin is much more expensive) and 1 gm/40 gm vancomycin.
   - Target likely-offending organisms [6]. Over the last 15 years in 231 infected elbows treated at Mayo Clinic: Coag – Staph – 22%; Staph A. 14% (data generated for this review – JSS).
   - A single low-dose gentamycin cement (1 gm/40 gm cement) may actually select an increase in coag – infections [6].
2. **Which cement should be used?**
   Palacos has better elution properties, but this does not seem to matter clinically.
3. **Will bacterial resistance develop?**
   No evidence of this to date [28].
4. **Will the altered mechanical properties of the cement affect loosening rate**?
   No evidence of this to date.

Authors: Raul Barco Laakso, Samuel Antuña

QUESTION 3: Does previous surgery (arthroscopic, fracture fixation, other non-arthroplasty) increase the risk of subsequent elbow periprosthetic joint infection (PJI) after total elbow arthroplasty (TEA)?

RECOMMENDATION: There is an apparent increase in the percentage of infections among patients with a previous operation in the affected elbow joint, though the association is not robust and needs to be further analyzed.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

A comprehensive literature search of three online databases (PubMed/Medline, the Cochrane database for clinical trials, and Embase) was performed using the following MeSH search terms: "elbow," "elbow joint," "joint prosthesis," "arthroplasty," "replacement," "elbow replacement," "elbow arthroplasty" and "elbow prosthesis."

Because of the evolution of TEA techniques, only articles published from January 2000 until September 2018 were reviewed. By the titles and abstracts, two reviewers independently identified potentially relevant articles for review of the full text. The reference lists of the included articles were manually checked to avoid missing relevant articles. When the entire text was obtained, the authors independently selected articles. Studies were not blinded for author, affiliation or source.

Inclusion and Exclusion Criteria

The included articles presented original data on patients who had undergone TEA. The diagnoses included the following indications: osteoarthritis, trauma/fracture, post-traumatic osteoarthritis, rheumatoid arthritis, hemophilia and other inflammatory diseases. Studies with a minimum duration of follow-up of two years and a minimum of five patients were included. Studies on revision operations were not included. Articles presenting the results of both revision and primary TEA were excluded unless the information for primary TEA could be extracted. Articles presenting the results for interposition arthroplasties, fully-hinged prostheses, hemiarthroplasty or partial resurfacing of the elbow were reviewed if they included information regarding the outcome of further treatment

with TEA with extractable outcome data. Review articles, expert opinions and surgical technique articles were excluded. When possible, studies comparing different groups were analyzed separately. The search was restricted to articles written in English, Spanish and French. Some articles that represent institutional historical databases were included only once.

Data Extraction

After the initial assessment for inclusion, two reviewers extracted data from the included articles. The primary goal was to determine the rate of infection after TEA and the pathogen responsible for determining the best potential antibiotic regimen.

The following parameters were recorded when available: numbers of patients and elbows, sex, age, design of TEA implant, indication for TEA (e.g., primary osteoarthritis, rheumatoid arthritis, fracture, post-traumatic osteoarthritis or other abnormality), whether the prosthesis was linked or unlinked, the rate of infection and the pathogen responsible. When prophylactic antibiotics were reported, they were recorded. Specific information regarding previous operations prior to arthroplasty was searched, as it was the focus of this review.

No other attempt was made to extract other data regarding other complications. Data regarding the number and type of surgical procedures before index TEA was collected and outcomes of these TEAs were extracted when available. Revision for infection was defined as removal of all or part of the arthroplasty or loosening that required removal regardless of the indication, or if a new TEA was implanted or excised.

Data and Statistical Analysis

Different groups were established by the preoperative regimen and the causative pathogen, when known. The outcome measures were the rate of infection and the distribution according to the pathogen. When sensitivity antibiotic analysis was performed, this information was also analyzed.

Methodological Quality

The two authors assigned the methodological quality of included studies according to the Center for Evidence-Based Medicine [1].

RESULTS

Articles

After the removal of duplicate articles, our initial search yielded 227 articles from Medline, Embase and Google Scholar. After title and abstract evaluation, a list of 56 articles was created for full review. After a full review, 35 studies were deemed suitable for further assessment and data collection.

There were no prospective case series and no randomized controlled trials. All were level IV evidence. Data were extracted into a standard worksheet for further analysis.

Prior procedures

Reporting of previous surgery before TEA was only available in six studies. Two hundred and one patients out of 291 (69%) were reported to have had prior surgery before TEA. The average rate of infection in these six studies was 11%, which is almost double to the reported rate of 5.5% in our concurrent systematic review (Table 1).

Kodde et al. reported on a series of 17 patients treated for post-traumatic arthritis with a cemented semi-constrained prosthesis, with a mean follow-up of 32 months. Fourteen patients had a prior operation consisting mainly in open reduction and internal fixation (nine cases, 64%), two patients had radial head resection, two had radial head prostheses implantation and one case had a medial epicondyle resection [2]. There was one case of infection (1%), but information is lacking regarding to which group it pertained. Additionally, the follow-up was short so that longer follow-up could increase the described rate of infection.

Baksi et al. reported on the use of a sloppy-hinge TEA for the treatment of fresh elbow fractures and non-unions. Eleven of the 41 cases reported had a previous failed internal fixation [3]. One of these patients suffered an infection that was treated with resection arthroplasty (1%) compared to one infection in 30 cases that did not undergo prior procedures (0.03%).

Throckmorton et al. reported on 84 patients with post-traumatic arthritis undergoing a semi-constrained TEA with a mean follow-up of nine years. The majority of this group of patients (90%) had prior surgery and the authors report seven deep infections without further information regarding the risk of preoperative surgery. The mean number of preoperative surgeries was three, so this group of patients may not be comparable to other studies [4].

Cil et al. reported the outcomes of a semi-constrained TEA for post-traumatic arthritis in 92 patients, of which 76 had previous surgery [5]. Of note, eight patients had a history of prior infection. At latest follow-up, five patients had an infection, all of which had had a previous operation. Interestingly, three of these patients had had a previous infection, so it is difficult to interpret if these were indeed a new episode or a reactivation of a latent infection.

Peden et al. reported on the outcome for TEA for an ankylosed or fused elbow, reporting 3 infections out of 13 cases [6]. One occurred perioperatively and the other happened at 2 and 15 years. Two of the three cases had previous surgery, but the type of surgery is not explicitly stated.

Sorbie et al. reported on a series of 44 unlinked TEA for hemophilic arthritis, rheumatoid arthritis or posttraumatic arthritis [7]. Sixteen patients had had a previous operation in the elbow and one of the seven infections occurred in a patient with post-traumatic arthritis and history of a previous operation. Once more, no reference to the number or type of previous operations was provided.

In a landmark paper, Morrey et al. reported on the outcome of 14 patients with an infection after TEA out of a group of 156 patients (9%) [8]. The rate of infection was 8 out of 99 patients without previous surgery compared to 6 out of 49 patients that had prior surgery (8% vs. 12.2%). This relationship was not statistically significant, alone. If only patients with previous surgery and rheumatoid arthritis were analyzed, the authors found a significant association, but the number of patients is so small that these findings should be interpreted with caution. Additionally, two of the patients with rheumatoid arthritis and prior surgery were on steroids.

The authors defined infection as deep sepsis that included different clinical and laboratory findings.

Conclusions

There is insufficient information regarding the influence of previous surgery on the incidence of infection after total elbow arthroplasty. Inadequate reporting regarding the number of procedures, the type of procedures and other patient-associated factors makes achieving definitive conclusions difficult. In a landmark paper, Morrey et al. highlighted the association of prior operation with the development of a periprosthetic joint infection after TEA. However, even though there is an apparent increase in the percentage of infections among patients with a previous operation, the association is not robust and needs to be further analyzed.

TABLE 1. Summary of information regarding the rate of infection after TEA when having prior surgery

Author, Year	Indication	Arthroplasty	Number of Cases	Number of Infections	% Infection	Number of Previous Surgeries	Additional Information
Kodde et al., 2013	PT	Coonrad-Morrey	17	1	5.8	14	None
Baksi et al., 2011	PT	Baksi sloppy hinge	41	2	4.9	11	1 infection in 11 PTs w/ prior surgery vs. 1/30 w/o prior surgery
Throckmorton et al., 2010	PT	Coonrad-Morrey	84	7	8.3	76	None
Sorbie et al., 2011	RhA/ PT/ Hemophilia	Sorbie	44	7	17%	16	1 infection with prior surgery (PT)/ 6 had infection immuno-suppression (RhA)
Peden et al., 2009	10 PT/ 3 RhA	Coonrad-Morrey	13	3	23%	8	2 of 3 infected had prior surgery
Cil et al., 2008	PT	Coonrad-Morrey	92	5	5.4	76	All 5 infections had prior surgery (3 had infection prior to index TEA)

PT, post-traumatic; RhA, rheumatoid arthritis; TEA, total elbow arthroplasty

Diagnosis

Authors: Ilya Voloshin, Theodore Blaine

QUESTION 1: Is there a role for preoperative joint aspiration in the evaluation of the painful elbow arthroplasty for periprosthetic joint infection (PJI)?

RECOMMENDATION: Preoperative joint aspiration can play a role in the evaluation of the painful total elbow arthroplasty (TEA) suspected for infection.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

In a patient with painful TEA and the presence of prosthetic loosening on the radiographs, PJI is high on the list of differential diagnosis. PJI remains one of the major failure modes for TEA. Joint aspiration has not been evaluated at length as a diagnostic test in TEA, with only a few studies examining its role and usefulness in the identification of infection of the joint [1–3]. Although joint aspiration has not been specifically evaluated as a diagnostic test in TEA, the value of this diagnostic approach has been proven in the workup of patients with hip and knee arthroplasty [4].

Gille et al. reported that in five of six infected elbows, positive joint aspiration cultures were found, and cultures of the sixth elbow, which had previously been treated with antibiotics, tested positive for infection at the time of revision [2]. There is little data on the role of joint aspiration in evaluating infection in TEA, however, it has been shown to be useful in identifying patients with PJI in hip and knee arthroplasty patients [4].

When aspirated, the obtained synovial fluid should be sent for white blood cell (WBC) count, with particular attention to the differential (% polymorphonuclear neutrophils). In addition, the fluid should be sent for aerobic and anaerobic cultures. Elevated synovial fluid WBC count is highly suggestive of PJI [5]. The hip and knee arthroplasty literature demonstrated excellent sensitivity and specificity of synovial WBC for the diagnosis of chronic PJI [6–11]. Based on that literature, the proceedings of the International Consensus on PJI recommends the following thresholds for synovial fluid tests for chronic PJI: WBC > 3,000 cell/microL and % PMN of 80% [12]. For acute PJI, the recommended thresholds are the following: WBC > 10,000 cell/microL and % PMN of 90% [12].

Gram stains lack sensitivity and specificity, and are not routinely recommended [13]. Cultures remain the most effective method for specific organism identification. However, despite a high specificity, culture has poor sensitivity and a negative culture does not rule out the diagnosis of PJI [14–18]. For isolation of the infecting organism, aerobic and anaerobic cultures of the obtained samples should be performed [19,20]. The addition of Acid-Fast Bacilli (AFB) and fungal cultures can also be considered in patients with atypical infection and a possibility for these infections. Additionally, incubating cultures for a longer period (21 days) may assist in identifying fastidious, slow-growing organisms such as *Cutibacterium acnes* [21].

Despite the lack of adequate studies in the TEA literature, and borrowing from the hip and knee arthroplasty, we recommend that aspiration of elbow joint suspected of infection should be part of the diagnostic work up. The synovial fluid obtained should be sent for routine culture (which may need to be kept for 14-21 days), WBC count, determination of neutrophil percentage and possibly molecular analyses for identification of the infective organisms.

QUESTION 2: What is the role for serum erythrocyte sedimentation rate (ESR), C-reactive protein (CRP) or white blood cell (WBC) count in the evaluation of an elbow arthroplasty for periprosthetic joint infection (PJI)?

RECOMMENDATION: ESR, CRP and WBC play a role in screening and monitoring for PJI, though evidence is limited regarding specific thresholds and strategies to guide the surgeon when interpreting these values.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 95%, Disagree: 0%, Abstain: 5% (Unanimous, Strongest Consensus)

RATIONALE

When in the evaluation stage of a suspected PJI, these laboratory markers are often combined with the clinical findings and joint aspiration to increase confidence of PJI [1–9]. In isolation, ESR and CRP may be difficult to interpret, especially in the setting of a medically complex patient with underlying conditions such as rheumatoid arthritis or with atypical infectious organisms such as fungi [2,3]. In monitoring for resolution of an infection after initial explantation, these laboratory markers are utilized again in concert with clinical factors, and it is important to trend these over time [5]. If the values have not normalized at the time of subsequent surgery with plans to reimplant, a repeat debridement and washout is advised along with the trending of values over time.

Despite the lack of multiple randomized clinical trials reflecting the utility of ESR, CRP and WBC measurement and monitoring in the patient with PJI of the elbow, several retrospective studies demonstrate the usefulness of integrating these values into the treatment plan. Also, the importance of these markers has been incorporated into the recommendations of the American Academy of Orthopaedic Surgeons for the treatment of PJI in the hip and knee [7,10]. This recommendation is rated as "limited" due to the lack of large, high-quality studies addressing PJI in the elbow specifically, rather than adapting already-published data from other joints, though these results are useful as they may be extrapolated to the management of elbow PJI.

QUESTION 3: What is the role of intraoperative histology examination in the evaluation of an elbow arthroplasty for periprosthetic joint infection (PJI)?

RECOMMENDATION: Intraoperative histology for the evaluation of elbow PJI in isolation is not sufficient for the diagnosis of infection.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 92%, Disagree: 4%, Abstain: 4% (Super Majority, Strong Consensus)

RATIONALE

There are a number of studies related to the use of histologic examination for the diagnosis of PJI in hip and knee arthroplasty [1–4]. The available literature suggests that although histology cannot be used as a standalone test for the diagnosis of PJI, it does provide valuable information in the work-up of patients with suspected PJI (in fact, the MusculoSkeletal Infection Society (MSIS) workgroup included histological examination as a criterion for its diagnosis) [5,6]. The controversy that exists is what constitutes a positive histology [4]. Currently, based on the MSIS criteria, the presence of more than five neutrophils in more than five high-power fields is indicative of positive histology. The latter is based on examination of periarticular tissues for the diagnosis of infection and the role of histology during reimplantation to assess the presence of persistence infection is less well studied.

The role of histology in the workup of patients with painful total elbow arthroplasty (TEA) is less well known. Our extensive search of the literature revealed only one study that specifically examines the subject of histology in the diagnosis of infected TEA [7]. This study was a retrospective analysis of 208 patients undergoing revision TEA. The sensitivity of histology in the diagnosis of PJI was 51.3%, with a specificity of 93.1%. The positive predictive value of histological examination was 60.6% with a negative predictive value of 90.2%.

Among the cohort, 65 (31%) did not have either histology or cultures taken at the time of revision, which raises the question of selection bias. The sampling sites of the histologic specimens were not standardized and were performed at the discretion of surgeon, averaging less than two samples per patient. Finally, the gold standard to define infection was the presence of a single positive intraoperative culture. Within these limitations, the data suggests that when intraoperative histology demonstrates acute inflammation (according to the criteria of Mirra et al. [8]) the probability of infection is high, but the absence of the acute inflammation does not rule out infection.

Based on the literature (mostly from hip and knee arthroplasty) and our understanding of the challenges that exist in the work-up of patients with painful TEA, we recommend that histological examination of tissues from around the elbow be part of the workup of patients undergoing revision TEA.

QUESTION 4: Is there a role for sonication of retrieved implants from an elbow in the diagnosis of a possible periprosthetic joint infection (PJI)?

RECOMMENDATION: At present, there is no evidence to support the routine use of sonication of removed elbow implants to improve the diagnostic accuracy or yield of cultures in the diagnosis of elbow PJI.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Sonication involves the application of high-frequency ultrasound (approximately 40 kHz) to a retrieved implant in an ultrasound "bath" of appropriate fluid medium. The liquid medium from the bath is then collected and centrifuged, and these aliquots are

cultured with conventional techniques. The concept is that organisms ensconced in a biofilm on the implant are loosened or released by this process, and are more readily cultured.

There was some promising initial evidence from retrospective reviews that the sonication process increased the number of positive cultures, especially in patients who had been receiving antibiotics, or those who had previously negative cultures despite clinical and serological evidence of infection. However, these studies focused on lower extremity arthroplasty. A paper by Holinka et al. noted improved diagnostic accuracy with sonication ($p = 0.008$) compared to conventional cultures, but none of the 60 patients studied had an elbow prosthesis [1]. Similarly, a study by Achermann et al. reported on only one elbow implant in 37 cases, which significantly limits the applicability of this information to the upper extremity [2].

There is only one study in the literature that is specific to the elbow. A review of 27 presumptively uninfected and 9 infected patients with a prosthetic elbow noted that while sonification of removed elbow arthroplasty implants had a sensitivity of 89% and a specificity of 100%, this did not differ significantly from the results of standard microbiological culture techniques at their institution (sensitivity 55%, specificity 93%, $p = 0.18$ and $p = 0.16$, respectively). While this may represent a "beta-error" in which a true improvement in the yield of sonication is obscured by insufficient numbers to prove statistically significance, in the eight years since this paper was published, we were unable to find a more definitive or compelling study [3,4].

A larger study of 53 shoulder arthroplasty patients examining the results of sonication of retrieved upper extremity implants has recently been published by Grosso et al. [5]. They found that the sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV) and accuracy of the cultures were not improved by sonication (US) when compared to standard (S) techniques: Sensitivity 96% (S) versus 96% (US), specificity 75% (S) versus 64% (US), PPV 77% (S) versus 71% (US), NPV 95% (S) versus 95% (US) and accuracy 85% (S) versus 79% (US). None of these differences were statistically significantly different. Additionally, it is well-recognized that the microbiological flora of the shoulder, and the subsequent infections that result from it, are distinctly different than that of the elbow. Therefore, it is not advisable to directly compare (or extrapolate the findings of) one joint to the other.

To conclude, at the present time there is insufficient evidence to either support or refute the utility of routine sonication of prosthetic elbow implants removed at the time of surgery in order to increase the yield or accuracy of cultures. Until a sufficiently-powered, prospective study has been performed demonstrating the efficacy of sonication to diagnose infection for revision elbow arthroplasty, we cannot support the routine use of this technology.

Authors: Mark Morrey, Shawn O'Driscoll

QUESTION 5: Do molecular markers have a role in the diagnosis of elbow periprosthetic joint infection (PJI)?

RECOMMENDATION: Despite the presence of data related to the use of molecular markers for the diagnosis of infection in hip and knee arthroplasty, the role of molecular markers in the diagnosis of total elbow arthroplasty (TEA) infection remains unknown.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

An extensive literature search was performed to identify publications related to the use of molecular techniques for the diagnosis of PJI in TEA. Our detailed search revealed numerous articles in total hip and knee arthroplasty. From our search, 180 articles were ultimately reviewed. A complete search of the abstracts, references and selectively full text from systematic reviews specific to TEA revealed there were only three studies with a total of only three elbows examining the use of molecular techniques to diagnose periprosthetic infection in TEA.

The alpha-defensin immunoassay and leukocyte esterase (LE) tests were recently reviewed in a systematic review and meta-analysis by Wyatt et al. [1]. In this review, six studies examined alpha defensin; however, no TEAs were included. Five of the included studies utilized LE for the diagnosis of PJI and only one of these included a single TEA out of 52 prostheses examined [2]. In their study, Colvin at al. found a sensitivity, specificity, positive predictive value and negative predictive value of 100, 97, 95 and 100% respectively [2].

In another systematic review, Suen et al. [3] compared the "quick test" version of alpha-defensin to the laboratory-based test, which further led to a study by Sigmund et al. [4] which included hip, knee, shoulder and elbow revisions done for pain or instability in 49 patients. These authors found a sensitivity and specificity of 69% and 94%, respectively, with a positive and negative likelihood ratio of 12.46 and 0.33, respectively. Again, unfortunately this study only included a single patient with an elbow arthroplasty PJI. The larger systematic review found a pooled

sensitivity and specificity of the laboratory assay to be 95 and 96% respectively, compared to the quick test lateral flow of 77 and 91%, respectively, but again, only a single elbow arthroplasty was included in the pooled group.

Finally, in a pilot study by Wouthuyzen-Bakker et al., synovial calprotectin was examined as a biomarker for PJI [5]. This test is attractive because of the low cost, the possibility to obtain a quantitative value, the use of a lateral flow assay with the possibility to use it as a point of care test and its availability, as it is already used in routine care for other indications in most hospitals. Unfortunately, while this study included TEA, no PJIs were included in the TEA group. The single elbow examined was in a control group without infection. This pilot study revealed that synovial calprotectin had an overall sensitivity, specificity, positive predictive value and negative predictive value of 89%, 90%, 81% and 95%, respectively.

Other biomarkers examined in a pooled meta-analysis by Lee et al. [6] included α-defensin, LE, interleukin (IL)-6 and IL-8. The overall sensitivity of these molecular tests was 85% compared to culture, which was 80%. Alpha-defensin in this study had the highest diagnostic odds ratio. Unfortunately, all studies included hip and knee arthroplasties and not a single study examined TEA.

Of significant note, despite their ability to identify PJIs with a high likelihood in most other joints, all biomarkers utilized in these studies require some element of polymorphonuclear cells to be present in the synovial fluid for detection. These tests do not discriminate between other inflammatory conditions and infection, which would be the most useful to surgeons. Specifically, as inflammatory conditions have historically been the primary indication for surgical intervention about the elbow, a test to discriminate between infection and other inflammatory conditions such as rheumatoid arthritis or gout does not yet exist.

Nevertheless, as these tests have shown promise in PJI in other joints, studies should be undertaken specific to the elbow. However, at this time conclusions are difficult to draw given the lack of clinical data specific to the elbow, which forms the basis of our recommendation.

QUESTION 6: What are the diagnostic criteria for elbow periprosthetic joint infection (PJI)? (Clinical criteria, radiographic criteria, intraoperative findings, pathology, cultures and serum biomarkers.)

RECOMMENDATION: The following three parameters provide a definitive diagnosis of elbow PJI:

- A sinus tract that is communicating with the prosthesis (Strength: Strong)
- Isolation of identical pathogens from two or more separate cultures (tissue or articular fluid) obtained under sterile conditions (Strength: Strong)
- Presence of intra-articular pus (Strength: Consensus)

The following criteria are concerning for infection and should be considered in aggregate (Strength: Limited):

- Warmth, redness, swelling of the elbow
- Elevated serum inflammatory markers (erythrocyte sedimentation rate (ESR), C-reactive protein (CRP)) – except in cases of inflammatory arthropathies
- Elevated synovial white blood cell (WBC) count
- Elevated synovial polymorphonuclear percentage
- Isolation of organism from one sample (tissue or articular fluid)
- Histologic evidence of acute inflammation
- Early unexpected component loosening
- Endosteal scalloping, rapid progressive loosening on radiographs

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 92%, Disagree: 8%, Abstain: 0% (Super Majority, Strong Consensus)

RATIONALE

The limited total number of total elbow arthroplasty (TEA) infections reported in the literature makes the assessment of preoperative factors consistent with infection challenging. In addition, limited early recognition of the role of low-grade, indolent infections (*Staph-*

ylococcus epidermidis, Cutibacterium acnes) may make interpretation of earlier studies challenging. Nonetheless, the literature provides valuable insights into the diagnosis of PJI in TEA.

Given the subcutaneous nature of the elbow, many infected TEAs do develop draining sinuses. This diagnostic criteria has been consistently used in the literature and was predictive of positive cultures in the vast majority of cases. In the review by Cheung et al. of 29 patients with PJI, 11 (38%) had draining sinuses [1]. Peach et al. showed a 38% rate of draining sinus, as well [2].

Culture growth was the most commonly-cited diagnostic criteria in the literature. Several studies considered a TEA to be infected in the presence of one positive culture [1,3–9]. Several other studies only made the diagnosis of PJI if two cultures were positive for the same pathogen [10–12]. The latter is consistent with the MusculoSkeletal Infection Society (MSIS) criteria [13]. In light of the publication by Wee et al. regarding "unexpected positive cultures," using the criteria of one positive culture for the diagnosis in the absence of other signs would likely over-diagnose PJI [14]. Therefore, one positive culture should be used in the constellation of other signs and symptoms of infection. If two cultures from two separate sources return the same pathogen, the diagnosis of PJI is supported strongly by the literature.

Numerous other criteria were used in the diagnosis of PJI. While these signs and symptoms were frequently seen, they were not seen with enough reproducibility to be diagnostic in isolation. Warmth, redness and swelling were consistently seen [15]. Elevated serum ESR and CRP, as well as aspirate WBC (and differential), and acute inflammation on intraoperative pathology were commonly seen in TEA PJI. However, many of the patients receiving a TEA have inflammatory arthropathy as their underlying diagnosis, leading to a substantial number of false positives. Furthermore, in the setting of low-grade infections, aspiration and serum laboratory studies are not accurate in isolation. These diagnostic criteria should be used in combination with clinical and radiographic assessments to assess likelihood of true PJI.

The radiographic appearance of the TEA and pace of loosening can provide insight into the likelihood of PJI. Early unexpected radiographic failures (< two years) are more likely to be consistent with PJI than late failures [14,16]. In addition, endosteal scalloping and rapidly progressive loosening were associated with PJI in TEA in most series in the literature [4,9,15].

Based on available literature, it is hard to make consensus quantitative assessments of number of criteria required from the "associated criteria" category. Certainly, based on the literature, an increase in the number of positive criteria increases the likelihood of true PJI.

Treatment

Authors: Mark Cohen, Robert N. Hotchkiss

QUESTION 1: Is there a role for irrigation and debridement with implant retention when treating acute elbow periprosthetic joint infection (PJI)? Should modular implant parts be exchanged?

RECOMMENDATION: Surgical debridement, antibiotic and implant retention (DAIR) is a viable option for management of acute elbow PJI. Modular implant exchange should be considered.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Total elbow arthroplasty (TEA) has historically been associated with a high risk of PJI. In 1983, Morrey et al. described this association and recommended the use of antibiotic-impregnated cement to reduce the risk of PJI after primary TEA [1]. Although infection rates have improved since then, PJI remains a potentially catastrophic complication of TEA. TEA implant revision is technically challenging, particularly given the relative lack of progress that has been made in TEA implant revision systems over the past 30 years. No comparative study exists to discern the superiority of DAIR versus explantation. Both strategies have been described, with varying degrees of success for both options [1–6].

Of the studies available for review, treatment recommendations varied. Given the variation in patient age and general health, bacteriology, mechanical circumstances, soft-tissue coverage and the retrospective nature of the study designs, it is difficult to make definitive recommendations about the indications for irrigation and debridement with retention of components. Alternative options include removal and reimplantation of new components in a single-stage or two-stage exchange with interval antibiotic cement spacer and resection arthroplasty.

Although no studies exist comparing DAIR with more invasive options, some patients do respond well to isolated irrigation and debridement [5]. There is extensive data to support the role of DAIR in the hip and knee arthroplasty literature. Because TEA systems rely on cement mantle fixation, explantation of well-fixed components leads to significant bone loss and morbidity.

Thus, DAIR may be offered to patients with infection of TEA in the presence of well-fixed components. The following general rules may need to be obeyed in performing DAIR in these patients.

1. If the components are well-fixed, removal of these implants will cause damage to the humerus and ulna, making the revision more challenging. Therefore, all attempts should be made to retain these using repeated irrigation and debridement, oral antibiotic suppression and soft-tissue coverage, even if that includes free tissue transfer.
2. If one component is found to be loose during DAIR, then the well-fixed component may be left in place while exchanging the other component.
3. In the presence of both components being loose, both components (and as much of the cement as possible) should be removed. An antibiotic-impregnated cement may be inserted with intravenous antibiotic treatment. The culture results would then dictate the length, dose and the type of antibiotic therapy needed.

Because resection arthroplasty leads to poor patient-reported outcome scores [6], we recommend that this option be reserved as a final "salvage" option after all other methods have failed or when the patient is not medically stable for two-stage exchange. Given the technical ease and low morbidity, we recommend that any modular components be removed and replaced in every case.

It is important to note that the method by which DAIR is performed influences the outcome of this surgical procedure. It is strongly recommended that clear margins for debridement of infected tissues are obtained, the modular components are taken out, the infected joint is irrigated copiously with antiseptic agents such as dilute betadine and the new modular parts are inserted after new drapes are used.

QUESTION 2: What are the indications for one-stage and two-stage exchange arthroplasty when treating an acute or chronic elbow periprosthetic joint infection (PJI)?

RECOMMENDATION: Two-stage exchange arthroplasty should be considered for patients with chronic elbow PJI. There are no clear indications for one-stage exchange arthroplasty for infected total elbow arthroplasty (TEA), but two-stage exchange is preferred in patients with sinus tract and/or compromised soft tissues around the elbow or those with systemic sepsis.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Treatment strategies for elbow PJI have generally taken four forms: debridement, antibiotic and implant retention (DAIR), one-stage exchange arthroplasty, two-stage exchange arthroplasty, and resection arthroplasty. While DAIR is reported to be successful, this discussion will focus on staged reconstruction [1,2].

The body of evidence to support one-stage exchange arthroplasty is very sparse, with only one retrospective case series reported in the literature. Gille et al. reported on six infected TEAs treated with one-stage exchange arthroplasty. The outcome was successful in five patients, with a follow-up period ranging from 6 months to 16 years. Outcomes indicated patient satisfaction in four of six patients and a mean Mayo Elbow Performance Score of 67 points [3].

The evidence for two-stage exchange arthroplasty is greater than for one-stage, but is also limited to retrospective case series (level IV evidence). In an initial report, Wolfe et al. performed successful two-stage exchange arthroplasty on one elbow in their series of 12 elbow PJIs [4]. Yamaguchi et al. reported successful treatment in four out of five patients with infected TEAs [5]. In a follow-up study of an expanded patient cohort, Cheung et al. found a 28% reinfection rate with two-stage exchange arthroplasty [6]. Finally, Peach et al. studied 26 elbows undergoing two-stage exchange arthroplasty and reported successful eradication in 23 patients (88%) [7]. Pooling of the data on two-stage exchange arthroplasty from the literature results in 59 unique patients with an 18% recurrence rate.

Many of the studies regarding treatment of infected TEAs include a mix of acute and chronic infections with a wide range of surgical treatments and antibiotic regimens. In the setting of acute infection with early diagnosis, some authors recommend DAIR [8,9]. Most of these studies emphasize the importance of sufficiently robust patient health, an adequate soft tissue envelope, a sensitive organism and use of local intra-articular antibiotic placement in addition to intravenous therapy. In particular, debilitated patients may be treated with chronic antibiotic suppression if they are not able to tolerate the proposed surgical course, while intractable infections or inadequate soft tissue sleeves can be managed with resection arthroplasty [2,10].

There are no studies comparing one-stage and two-stage exchange TEA in similar patient populations. Achermann et al. studied 27 elbow PJIs, but most were treated by DAIR. In this series, one patient with a delayed infection was treated with one-stage exchange and two late infections with two-stage exchange arthroplasty. All three patients in this series had successful eradication of infection [9]. Spormann et al. reported on three late (> 24 months) and one acute (< three months) elbow PJIs treated with two-stage reconstruction (all were cleared of infection). Similarly, a one-stage exchange was used in one patient with a delayed (3 to 24-month) TEA infection, which was also successful [8]. Finally, in a review article Somerson et al. found inadequate data to recommend one-stage reconstruction, but reviewed the relative success of two-stage exchange arthroplasty with eradication of infection in 72-88% of patients [10].

Given the paucity of data surrounding one-stage exchange elbow arthroplasty, it is difficult to recommend an indication for this approach in the setting of elbow PJI. Though evidence overall remains limited regarding two-stage exchange, we conclude that this approach is currently favored for the treatment of acute and chronic infected TEA.

QUESTION 3: Is there a role for preoperative joint aspiration prior to second-stage revision after treatment of elbow periprosthetic joint infection (PJI)?

RECOMMENDATION: Preoperative joint aspiration may play a role in the evaluation of the elbow arthroplasty for PJI before second-stage revision.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 96%, Disagree: 0%, Abstain: 4% (Unanimous, Strongest Consensus)

RATIONALE

There are no studies that specifically investigate and prove that there is a role for preoperative aspiration of the elbow prior to second-stage revision arthroplasty. However, in a review of published studies that have addressed total elbow infection, aspiration was found to be the standard of practice in these studies. Furthermore, there is a logical rationale that preoperative aspiration provides useful information for both the diagnosis and treatment of total elbow arthroplasty (TEA) infections. When the risk factors for infection are higher (such as in patients with diabetes, obesity or rheumatoid arthritis), preoperative aspiration prior to second-stage revision has an even stronger recommendation. Currently, no evidence exists regarding what constitutes a positive aspiration. Therefore, the significance of the results should be assessed on a case-by-case basis.

Rudge et al. discussed the management of infected elbow arthroplasty by two-stage revision in 19 patients managed at their center [1]. In their algorithm for management, the authors state, "If the infective organism and sensitivities had been identified before the first stage, further antibiotics were added as necessary. If at the six-week postoperative review there were clinical signs of ongoing infection or inflammatory markers had not normalized, an aspiration was performed. If the aspirate analysis was positive, then patients underwent a repeat first-stage procedure (debridement and washout). If the aspirate analysis was negative, then a second-stage procedure was planned, but with a low threshold for making an intraoperative decision to repeat the first stage rather than re-implanting prosthetic components, if concerned about possible ongoing infection." These authors therefore recommend aspiration prior to second-stage revision as a means of determining when to proceed to the second stage, what procedure to perform and which antibiotics to use.

Using this protocol, the authors were able to treat the majority of TEA infections successfully — "Of the 19 patients undergoing a first-stage procedure, 16 (84%) remained infection free, of whom 11 had proceeded to a second stage and five had not. Of 14 patients undergoing a two-stage revision, 11 (79%) remained infection free. Of patients requiring further surgery due to recurrent infection, 2 (67%) remained infection free after a repeat two-stage revision, with the third patient still awaiting the second-stage procedure."

When aspiration is performed, the joint fluid should be evaluated for white blood cell (WBC) count, with particular attention to the differential (polymorphonuclear percentage). In addition, the fluid should be sent for aerobic and anaerobic cultures. Gram stains lack sensitivity and specificity and are not routinely recommended [2,3]. Cultures remain the most effective method for specific organism identification. The addition of Acid-Fast Bacilli (AFB) and fungal cultures should be performed if there is concern for atypical infecting organisms. Additionally, incubating cultures for a longer period (21 days) may assist in identifying fastidious organisms such as *Cutibacterium acnes*.

QUESTION 4: What is the role of permanent resection when treating a chronic elbow periprosthetic joint infection (PJI)?

RECOMMENDATION: Permanent resection is a salvage treatment for chronic elbow PJI. Preservation of medial and lateral condyles should be considered to improve functional outcomes.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Methodology

A comprehensive literature review was performed to identify all studies on permanent resection treatment for elbow PJI. Searches for the terms "elbow," "total elbow arthroplasty," "infection," "periprosthetic," "permanent resection" and "resection arthroplasty" were performed on the PubMed/Medline, Cochrane, Google Scholar and Embase databases through March of 2018. Our systematic review includes English studies (only level IV evidence) regarding permanent resection treatment for the elbow PJI. Non-English studies, technique papers without patient data, studies with inadequate patient follow-up and studies regarding resection treatment for non-elbow PJI were not included. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analysis) statement was followed for this review.

Discussion

PJI is a serious complication of total elbow arthroplasty (TEA) and is difficult to treat [1,2]. Treatment options include debridement with retention of implants, single or two-stage reimplantation, permanent resection and arthrodesis [1–5]. There are only a few studies with limited evidence comparing the outcomes of these treatment procedures [3–7]. Many authors have emphasized that good functional outcomes are only possible with reimplantation [8,9]. However, the success of the reimplantation treatment depends on remaining bone stock [9,10]. On the other hand, high recurrence rates of infection limits the success of the treatment [8]. Arthrodesis and permanent resection are defined as a salvage procedure in low-demand patients [1,2,5,7]. However, arthrodesis has a very limited role in the treatment of this circumstance, even as a salvage treatment, as it often results in a painful nonunion or infection recurrence [3].

Permanent resection is suggested as a salvage procedure for the treatment of elbow PJI in patients in whom debridement and reimplantation therapy had failed or in medically frail patients [2,7]. Rhee et al. reported that infections in nine patients (90%) could be eradicated with permanent resection for elbow PJI [11]. Despite the high successes of eradication of the infection, it was noted that sufficient stability was essential for the successful functional outcomes. It was emphasized that the condyles which articulate with the olecranon fossa are important for the stability in resection arthroplasty. Moreover, the authors have examined the role of poor bone stock in the condyles (which is common in this patient group) on the success of resection arthroplasty. It has been reported that the best functional results were obtained in patients in whom both condyles could be preserved, whereas the weakest functional results were reported to be obtained in the group of patients in whom only the medial condyle could be preserved. Figgie et al. reported that achieving stability has a key role in the success of resection arthroplasty following failed TEA [12]. Therefore, the authors emphasized that the epicondyles should be preserved.

In a study by Zarkadas et al., resection arthroplasty has been defined as an effective salvage procedure [1]. This study appears to be noteworthy due to fact that it reported the long-term outcomes of 29 patients (30 elbows) after resection arthroplasty for the failed TEA (11 years, range 2.7 to 28 years). In the study, it was noted that the increase in the Mayo Elbow Performance Score was reported to be mostly in the pain component, whereas the stability was directly related to good functional outcomes. However, the authors reported complications such as persistent infection in 24 elbows (47%), intraoperative fracture in 18 elbows (35%) and permanent nerve injury in 9 elbows (18%).

Specifically, the difficulties experienced during removal of the well-fixed humeral component were thought to be responsible for the high complication rates. For this reason, the authors suggested performing an osteotomy in the form of a trapezoidal window, which has a larger distal border in order to facilitate removal of the humeral component and cement. In addition, the authors pointed to the importance of the development of soft tissue scar utilizing a brace or a cast for a minimum of six weeks to surpass instability, which is thought to be responsible for the poor functional outcomes.

PJI following an elbow arthroplasty has a reported rate ranging from 22 to 41%, based on limited literature [1,2]. Diagnosis of chronic elbow PJI has remained a challenge, however, as many presentations are subclinical in nature, leaving cultures still as the recommended diagnostic tool [3]. Treatment of elbow PJI has primarily centered on intravenous antibiotics, debridement and retention as well as staged reimplantation, all of which have been proven to be relatively successful under the right indications [3–5]. There is limited literature regarding the success of this treatment modality. Permanent resection may be considered if previous attempts to resolve elbow PJI fail [3,6,7]. Zarkadas et al. found that 47% of their case series required additional surgery after permanent resection to resolve the infection [6].

There are no level I or II studies available, though one level III and two level IV studies exist examining permanent resection as a treatment modality for chronic TEA PJI. Both level IV studies are case series with sample sizes of 51 and 10 patients, respectively [3,7]. Both level IV studies demonstrated that successful eradication of PJI is heavily dependent on surgical technique and more experienced TEA surgeons are correlated with higher eradication rates for elbow PJI via permanent resection.

One study reported patient outcomes and showed higher functional Disabilities of the American Shoulder and Hand scores with resolution of elbow PJI via permanent resection [6]. Therefore, even with the paucity of literature available, permanent resection should be considered for chronic elbow PJI that fails to respond to other treatment modalities.

In brief, the permanent resection has been suggested for frail patients with low functional demands or for patients who are not interested in additional reconstructive surgeries [1,2,7,11]. The aim of treatment should be the eradication of infection, relief of pain and improved functions [1,4,11]. Contrary to what is known, persistent infection is a frequent complication [8]. Given this finding, all of the infected tissue and foreign materials should be removed [1,7,11,12]. However, aggressive debridement and removal of the well-fixed implants result in loss of bone stock [1,11]. This condition increases the instability risk which is directly correlated with poor functional outcomes [1]. Both condyles should be preserved as much as possible so that a new effective fulcrum might be created, which would make it possible to achieve a stable new elbow joint [8,9,11]. In order to achieve favorable functional outcomes and soft tissue stability, the integrity of the triceps mechanism should be preserved [12] and immobilization should be ensured for a minimum of six weeks postoperatively by casting or bracing [1].

QUESTION 5: What is the role of arthrodesis when treating a chronic elbow periprosthetic joint infection (PJI)?

RECOMMENDATION: There is a very limited role for arthrodesis of an infected elbow, as this procedure usually results in painful nonunion and poor functional outcomes.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

The incidence of deep infection after total elbow arthroplasty (TEA) has been reported to be 3–13.3% [1–4]. It has been widely accepted that elbow PJI is difficult to treat and has poor outcomes [1,2,5]. Compared to knee and hip arthroplasties, relatively high infection rates [2] and poor outcomes [6] have led to an assessment of the efficacy of different treatment procedures [2,5]. Treatment modalities include debridement with prosthetic retention, resection with subsequently staged reimplantation, staged reconstruction with composite allograft, permanent resection and arthrodesis [2–9].

Among the aforementioned treatment modalities, arthrodesis must be the last choice and should be regarded as a salvage procedure. Functional limitation after arthrodesis cannot be compensated by adjacent joints [8,10,11]. Small contact areas of the remaining bone stock and high moments generated by the long lever arm preclude obtaining solid bone fusion [8,11,12]. Even if fusion can be achieved, it has been reported that humerus fracture risk increases in longer follow-up [13]. Arthrodesis has been reported to be a successful treatment only if there is adequate bone stock, good soft tissue envelope and sufficient vascular supply [8,14,15]. However, in majority of patients with elbow PJI, there are bone defects due to the destructive effect of infection, removal of bone as part of treatment of infection, vascularity is impaired and soft tissue coverage may be insufficient secondary to recurrent surgical interventions [2,5,12–16].

Wolfe et al. described two patients treated with arthrodesis after elbow PJI [9]. The authors reported a painful fibrous union in one patient and a persistent infection in the other. In the limited literature evaluating the treatment of arthrodesis after elbow PJI, the largest series (by Otto et al.) consists of five patients [11]. The authors reported that no union was achieved in any of the patients, and there was asymptomatic fibrous union in only two patients (40%) at the last follow-up. In that study, high reoperation rates and high complication rates were emphasized, and arthrodesis was not recommended for the elbow PJI.

Severe bone loss in this patient group was seen as an important cause of treatment failure. Thus, Koller et al. described an arthrodesis technique using double fibular strut graft and reported favorable results in a patient at the 12-month follow-up [10]. The arthrodesis of the radius to the humerus described by Presnal et al. aimed to surpass nonunion caused by the massive bone loss in the ulna [8]. Nevertheless, according to widely accepted view, arthrodesis treatments for the elbow PJI have poor outcomes and high reoperation rates, and it is not recommended except in special conditions [4,9,14–18]. It might be considered in the case of a failure of resection arthroplasty due to instability [15,17], especially when control of sepsis due to the mobility of the articulation is not possible [14] and also in young patients who do heavy bodily work [18]. Because of the limited literature and small case series, the role of arthrodesis in the treatment of elbow PJI could be evaluated with a limited level of strength.

Treatment of elbow PJI has centered on antibiotics, surgical debridement and retention or staged reimplantation [1]. In some cases where the joint is extremely damaged or seems unsalvageable, arthrodesis may be a viable treatment choice to avoid amputation [1]. Traditionally arthrodesis of the elbow has only been used when all other motion-preserving interventions are declared not possible and studies have reported elbow arthrodesis results in more impairment than hip, knee or ankle joint arthrodesis [2,3]. Koch and Lipscomb report that arthrodesis should be considered only when there is sufficient tissue damage to prevent reimplantation following TEA PJI, and in these cases they reported a 15% delayed complication rate [13].

Literature examining the success of elbow arthrodesis for chronic PJI is limited. There have been no level I, II or III studies, and only two level IV studies have examined the use of arthrodesis for chronic elbow PJI related to tuberculosis [5,6]. A recent review article suggested that evidence to support the use of arthrodesis is

incomplete as a treatment modality for chronic elbow PJI [11]. One aspect that should be taken into account is the technique used during arthrodesis, as Sala et al. found this influences the functional outcome following elbow PJI [19]. Overall, due to the limited literature, we cannot recommend the use of elbow arthrodesis to treat chronic elbow PJI.

QUESTION 6: Should all foreign material (including cement) be removed during resection arthroplasty of an infected elbow?

RECOMMENDATION: When treating elbow periprosthetic joint infection (PJI), attempts should be made to remove all foreign material. However, the benefit of removing all foreign material should be weighed against the effort to preserve bone stock.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Surgical management of an infected total elbow arthroplasty (TEA) is dependent on the chronicity of the infection and the infecting organism, as well as host factors. The majority of TEA components are placed in a cemented fashion. In cases where the humeral and ulnar components are removed, the cement mantle may or may not be easily extractable at the time of surgery. This discussion will focus on the literature which reports on patient outcomes following TEA component resection with retained foreign material.

A systematic review was performed using the search terms, "retained cement AND total elbow arthroplasty NOT shoulder." This search yielded zero results. Therefore, a broader search criterion was utilized. The second search evaluated "total elbow arthroplasty AND infection AND removal NOT shoulder." All 32 articles were reviewed. Of these, only one paper documented retained cement in the setting of removal of the humeral and ulnar components. Stoodley et al. [1] reported a single case series of a TEA performed for a distal humerus fracture nonunion. The patient underwent multiple staged operations including before and after the index TEA. Cultures remained negative until the seventh operation, when the authors noted a positive culture and documented that retained cement was removed at that time. However, the authors were unable to state if the retained cement was the cause of persistent infection, as the patient had not previously received targeted antibiotics that effectively addressed the infectious antimicrobial profile.

Given the lack of evidence available within the total elbow arthroplasty literature, information regarding the effect of retained cement must be taken from other orthopaedic literature. Early reports in the lower extremity arthroplasty literature raised concern about the correlation of retained cement and incomplete eradication of infection [2]. However, not all series have correlated retained cement with persistence of infection [3,4]. Petty et al. reported on 54 total hips treated for PJI. At the time of revision surgery, the presence of retained cement was not associated with positive intraoperative cultures.

Given the lack of data available in the elbow arthroplasty literature, we are unable to make a recommendation regarding the necessity to remove all cement or other foreign material in the treatment of periprosthetic TEA infections.

QUESTION 7: Is there a role for chronic antibiotic suppression in the management of elbow periprosthetic joint infection (PJI)?

RECOMMENDATION: Long-term suppressive antibiotics may be used in the treatment of PJI of the elbow. Consultation with an infectious disease specialist should be considered in the decision to use long-term suppressive antibiotics.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Treatment strategies for elbow PJI have generally taken four forms; irrigation and debridement with component retention, one-stage exchange arthroplasty, two-stage exchange arthroplasty and resection arthroplasty. Each of these treatment options may be followed by the use of suppressive antibiotics [1].

A systematic review was performed using the terms "elbow arthroplasty AND chronic suppressive antibiotics." This revealed zero results. A second search using the terms "infected elbow replacement AND suppressive antibiotics" produced no results. A third search using the terms "infected elbow AND chronic suppressive antibiotics" produced zero results.

A fourth search using the terms "chronic suppressive antibiotics AND elbow infection" produced a single result: "Gram-Negative Prosthetic Joint Infection: Outcome of a Debridement, Antibiotics and Implant Retention Approach. A Large Multicentre Study" [1]. In this multi-center study from Spain, there were two elbow PJIs out of 242 PJIs managed with debridement and chronic suppressive antibiotics (the other 240 patients included 150 hip, 85 knee and 5 shoulder). They reported 79% successful outcomes. Ciprofloxin exhibited a protective effect and chronic renal impairment predicted failure.

A final search with the terms "chronic suppressive antibiotics AND total joint infection" produced 12 results. Only one study (the previously-cited Rodriguez-Pardo article) included elbow replacement patients. Given the lack of evidence specific to PJI of the elbow, the only evidence available is contained in articles related to PJI of other joints. Aboltins et al. published a review citing a 77% success rate using rifampin-based therapy [2]. These two articles provide the most recent evidence in the use of antibiotic suppression in the treatment of PJI of the elbow. There are several other articles, primarily on hip and knee, and two are referenced that provide further evidence in support of suppressive antibiotic therapy [3,4].

In the absence of concrete data and given the complexity of removing well-fixed cemented components of total elbow arthroplasty, we believe suppressive antibiotic therapy may have more of an expanded role in these patients than in PJI affecting other joints.

PART VI

FOOT AND ANKLE

Prevention

1.1. PREVENTION: TOTAL ANKLE ARTHROPLASTY-SPECIFIC

Authors: Eric Senneville, Amiethab Aiyer, Niall Smyth

QUESTION 1: What are the important risk factors that predispose a patient to infection after total ankle arthroplasty (TAA)?

RECOMMENDATION: There is evidence indicating that the following risk factors may predispose a patient to an infection after a TAA: inflammatory arthritis, prior ankle surgery, body mass index (BMI) < 19 and peripheral vascular disease. Meanwhile, there is conflicting evidence (which may be due to patient selection bias) indicating that the following risk factors may predispose a patient to infection after a TAA: obesity (BMI > 30), tobacco use, diabetes, duration of surgery, age < 65 years, hypothyroidism, low preoperative American Orthopaedic Foot and Ankle Society (AOFAS) hindfoot score and chronic lung disease.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE:

The purpose of TAA is to eliminate pain while restoring some functional range of motion. One of the dreaded complications of TAA is a periprosthetic joint infection (PJI). The reported rate of this complication ranges between 0-8.9% [1–4]. Appropriate patient selection could be facilitated by understanding the preoperative risk factors for PJI.

Inflammatory arthritis is one of the patient characteristics that have been identified by two separate studies as a risk factor for PJI. In a retrospective comparative series, Raikin et al. followed 106 patients who had undergone a TAA and identified nine patients who necessitated a return to the operating room for an irrigation and debridement and/or removal of their hardware [5]. The authors concluded that an underlying diagnosis of inflammatory arthritis was a significant risk factor leading to the complications studied. Of note, patients with inflammatory arthritis showed a 14.03-times increased risk of requiring reoperation. Althoff et al. reached a similar conclusion in a database comparative study [6]. The authors used a national insurance database to select 6,977 TAA patients and assess which factors correlated with an increased risk of PJI within the first 6 postoperative months. Several risk factors were highlighted, one of which was a diagnosis of inflammatory arthritis.

A history of prior ankle surgery has been identified as a risk factor for PJI. Patton et al. retrospectively reviewed the cases of 966 patients who had a TAA and found 29 instances of postoperative infection [7]. Prior surgery of the ankle was found to correlate with an increased risk of PJI. In a comparative cohort study, Kessler et al. evaluated 26 demographically matched patients who developed PJI, the authors concluded that prior ankle surgery increased the risk of infection [1].

Age < 65 years (odds ratio (OR) 1.61), a BMI < 19 (OR 2.67), peripheral vascular disease (OR 2.46), chronic lung disease (OR 1.51) and hypothyroidism (OR 1.32) were all determined to be a risk factor for PJI following TAA in a single study [6]. Low preoperative AOFAS hindfoot scores were also identified as a risk factor by a single study [1]. These findings, however, have not been corroborated by other publications.

There is conflicting evidence in the literature regarding the role of obesity in TAA. A single database study identified a BMI > 30 as a risk factor for developing PJI [6]. This, however, is contradicted by two separate retrospective comparative series. Schipper et al. assessed the outcomes between 49 obese patients and 48 non-obese patients following TAA [8]. While the authors noted that there was decreased survivorship of the implant in the obese patient population, there was no increased risk of infection. Similar findings were noted in a large case series comparing patient-related factors between TAAs that developed infection and those that did not [7].

Whether tobacco use is a risk factor for PJI is not clear based on the current literature. The database publication by Althoff et al. concluded that smoking increases the risk of a PJI (OR 1.59) [6]. Lampley et al. compared the postoperative outcomes between nonsmokers (n = 359), former smokers (n = 249) and current smokers (n = 34) [9]. The authors concluded that while the active smokers had an increased rate of PJI, this did not reach statistical significance. Patton et al. however, concluded in their large case series that there was no association between tobacco use and postoperative infection following TAA [7].

The current literature is divided on the issue of whether diabetes is considered a risk factor for PJI [6–8,10]. The publications by Althoff et al. [6] and Patton et al. [7] both conclude that diabetic patients are at increased risk of infection. Further, Schipper et al. reached a similar conclusion that diabetes was an independent risk factor [9]. However, Gross et al. assessed the complication rate between 50 diabetic patients and a control group and concluded that diabetes did not increase the risk of infection [10]. Additionally, the length of the operative procedure is a risk factor that has shown some variance in the literature. Kessler et al. reported that the duration of the surgery was significantly longer (119 minutes) in the infected group, compared to the age and sex-matched control group (84 minutes) [1]. In contrast, Patton et al. found no difference in operative times between patients who developed a PJI and those who did not [7].

QUESTION 2: Does intra-articular injection of the ankle with corticosteroids increase the risk of subsequent periprosthetic joint infection (PJI) following total ankle arthroplasty (TAA)? If so, how long after a prior intra-articular injection can TAA be safely performed?

RECOMMENDATION: Every intra-articular injection of the ankle is an invasive procedure associated with potential healthcare-associated infections, including periprosthetic joint infection (PJI) following TAA. Based on the limited current literature, the ideal timing for elective TAA after corticosteroid injection for the symptomatic native ankle joint is unknown. The consensus workgroup recommends that at least three months pass after corticosteroid injection and prior to performing TAA.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 92%, Disagree: 8%, Abstain: 0% (Super Majority, Strong Consensus)

RATIONALE

Intra-articular steroid injections may transiently relieve the pain of osteoarthritis of the ankle and are widely used for its treatment. At the same time, every injection is an invasive procedure and might be associated with health-care-associated infections, including PJI following TAA. Seror et al. noted that the risk of septic arthritis after an intra-articular steroid injection is 1 in 70,000 [1]. For native ankle joints, one study found a 3.9% infection risk when using intraoperative steroids versus a 1.8% infection risk when performing arthroscopy without steroids [2]. However, this study was not related to TAA, and many other studies in native ankle joint arthritis deny a relationship with steroid injections.

The available literature investigating the effect of intra-articular corticosteroid injections on postoperative PJI are all in hip and knee arthroplasty patients. Some studies find no relationship between corticosteroid injections and infection [3–6], while others find an increased risk of deep infection following intra-articular injection [7–11]. Studies that find a positive correlation also suggest that timing may be an important factor, and that injections more closely preceding surgery may lead to an even higher risk of infection.

Unfortunately, there are no published data in regards to the risk of PJI after steroid injection in the setting of TAA. The data from hip and knee arthroplasty may not be applicable to TAA, and further studies are warranted.

QUESTION 3: Should routine methicillin-resistant *Staphylococcus aureus* (*S. aureus*), or MRSA, screening be in place prior to total ankle arthroplasty (TAA)?

RECOMMENDATION: Unknown. The role of screening for MRSA and decolonization prior to TAA remains unclear. Further data is needed to support this practice in TAA, which can be costly and logistically difficult to implement.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

There is growing concern about the increase of postoperative infections due to antibiotic-resistant organisms [1], and this is particularly important in orthopaedic surgery where the increasing incidence of antibiotic-resistant *Staphylococci* threatens the outcome of implant-related procedures. The complication rate and cost of periprosthetic joint infection (PJI) associated with MRSA is considerably higher compared to those associated with methicillin-sensitive *Staphylococcus aureus* (MSSA) [2]. Patients receiving orthopaedic implants are most vulnerable, given the potential for biofilm formation and long-term morbidity [3].

Furthermore, the prevalence of surgical site infections (SSIs) as a result of MRSA has increased over the last few years. Between 1992 and 2003, the prevalence of MRSA increased from 32% to 64% of all isolated nosocomial pathogens found on patients in hospital intensive care units (ICUs), representing a 3.1% increase in MRSA prevalence per year [4].

The last two decades have seen an increase in community-acquired MRSA (CA-MRSA), a subpopulation of MRSA with unique antibiotic resistance properties, high virulence characteristics and pathogenic capability. This subset of MRSA tends to affect young and otherwise healthy patients [5–7].

Several screening strategies have been studied in terms of their cost-effectiveness [8,9]. As the *S. aureus* strain isolated from SSIs commonly matches (in up to 85% of cases) the *S. aureus* strains sampled from the noses of colonized patients, nasal swabs emerge as a potentially cost-effective screening option [10–12].

However, the evidence is not conclusive regarding an association between rapid screening and the acquisition rate for MRSA or risk of MRSA-induced SSIs. However, in the setting of a positive result, it allows for the implementation of a decolonization protocol that is indeed effective in significantly reducing the rate of SSIs caused by MRSA [7].

A recently published, large multicenter prospective cohort trial by Schweizer et al. involving > 40,000 unique operations examined the effect of the introduction of a standardized preoperative *S. aureus* screening and decolonization program on deep *S. aureus* SSIs in cardiac surgery and hip and knee arthroplasties performed at 20 hospitals [13]. The authors reported that the hip and knee arthroplasty cohort demonstrated a significant reduction in postoperative rates of deep infection with *S. aureus* following the introduction of the screening and decolonization program.

Numerous studies have demonstrated that the most common pathogens in SSIs following total hip arthroplasty/total knee arthroplasty (THA/TKA) are MSSA and MRSA. Additionally, many of these studies have demonstrated that positive colonization correlates with increased SSIs and multiple studies have demonstrated the benefit of treating patients who test positive on preoperative screening. When assessing the cost-effectiveness of screening and decolonization, multiple studies have shown potential to substantially reduce the cost of THA/TKA by decreasing the rate of SSIs. Lastly, recent studies have demonstrated cost-effectiveness in universal decolonization programs with or without the inclusion of preoperative *S. aureus* screening. The latter has become a reality as numerous non-antibiotic agents have been introduced.

In the absence of concrete evidence supporting MRSA screening and decolonization in patients undergoing TAA, perhaps consideration should be given to universal decolonization of these patients using one of these non-antibiotic agents.

QUESTION 4: What preoperative optimization should be implemented to reduce the risk of surgical site infection/periprosthetic joint infection (SSI/PJI) in patients undergoing total ankle arthroplasty (TAA)?

RECOMMENDATION: We recommend that patients awaiting TAA be optimized prior to surgery by implementing skin cleansing, nutritional status enhancement, glycemic control, body mass index (BMI) optimization, smoking cessation, and management of immune-modulating comorbidities.

At the time of surgery, there is strong evidence that optimal preparation of the surgical site with an alcohol-containing agent, weight-based and timely administration of antibiotic prophylaxis, and reducing operating room traffic should also be put in place.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RESPONSE

PJIs complicating total joint arthroplasty (TJA) are potentially catastrophic events to patients and immense financial burden to the healthcare system [1,2]. These events can occur intraoperatively, immediately postoperatively or as a late complication via direct or hematogenous spread of pathogens to the prosthetic joint. The prevention of this potentially serious complication should always be a priority, and this is best achieved by the implementation of proper preventive strategies. Though preoperative optimization prior to TAA is limited in the literature. We recommend utilizing similar methods proven to prevent infection after total knee and hip arthroplasty.

In an attempt to decrease SSIs caused by *Staphylococcus aureus* (*S. aureus*), or MRSA, Alexander et al. recommended the use of chlorhexidine footbaths in patients with nasal colonization of *S. aureus* beginning five days prior to their foot and ankle surgery in addition to standard operative disinfection protocols [3]. Colling et al. demonstrated that a preoperative antiseptic shower and bath policy was associated with a significant decrease in *S. aureus* and MRSA SSI [4]. Despite being a valid option in preventing *S. aureus* and MRSA infections, this shower and bath policy failed to achieve a decrease in the total incidence of SSI. Prior to the procedure, prophylactic antibiotics such as cefazolin can be administered to patients, as this is considered an essential part of the foundation of SSI prevention due to its long-accepted reduction of infection in orthopaedic procedures and a current recommendation from the American Academy of Orthopaedic Surgeons [5–7]. Interestingly, in their retrospective study comparing the use of antibiotic prophylaxis either 15-60 minutes or less than 15 minutes prior to foot and ankle surgeries, Tantigate et al. found that the timing of intravenous antibiotic prophylaxis did not play a significant role in the risk of developing SSI [5].

In addition to external preventative measures, optimizing the nutritional status of patients undergoing TAA to optimize the immune system is important. Several studies on infections following orthopaedic procedures have demonstrated that a lymphocyte count below 1,500 cells/mL, an albumin level below 3.5 g/dL, a zinc level below 5 mg/dL, and a transferrin level below 200 mg/dL have been associated with increased risks of infection and delayed wound healing [8–12]. Therefore, nutritional parameters should be measured in those suspected of being malnourished and the abnormal parameters corrected prior to elective arthroplasty.

The optimization of medical comorbidities should also be considered an essential part of the preoperative protocol aimed at reducing PJI following TAA. Marchant et al. reported that the current glycemic control of patients with diabetes mellitus (DM) is more important toward the risk of infection following TJA rather than the diagnosis of DM itself, as the risk of infection of diabetic patients with controlled glucose levels was the same as patients without DM [13]. In their study on total hip and knee arthroplasties, Mraovic et al. further concluded that blood glucose levels immediately prior to and after surgery were significantly correlated with subsequent infection risk. These authors reported that non-DM patients with blood glucose levels greater than 140 mg/dL on the morning following surgery had a three-fold increase in infection risk [14]. Therefore, proper glycemic control in all patients should be performed in order to decrease the risk of SSI and PJI.

As obesity has been consistently shown to be associated with SSI risk in total hip and knee arthroplasties, especially BMI > 30 kg/m^2, weight reduction strategies leading up to surgery as well as dose-based antibiotic prophylaxis immediately prior to surgery in obese patients should be performed [1,15,16].

Certain other comorbidities are also highly related to an increased risk of infection in TJA due to decreased patient immunity, and these should be taken into consideration prior to surgery [1]. In their investigation into patient-related risk factors for PJI following TAA, Althoff et al. reported that, in addition to DM and obesity, a BMI < 19 kg/m^2, tobacco use, inflammatory arthritis, peripheral vascular disease, chronic lung disease and hypothyroidism were independent risk factors for PJI development following TAA [17]. Therefore, smoking cessation and optimization of these other aforementioned medical comorbidities should be performed prior to surgery. In their discussion of infection reduction following TJA, Matar et al. recommends this optimization of patient health through a preoperative evaluation by an internal medicine consultant or cardiologist, who subsequently follows the patient throughout their hospital course and postoperative period [18].

In the period immediately prior to surgery and within the operating room, we recommend utilizing the specific measures reported by Illingworth et al. and Matar et al. regarding infection minimization in TJA [1,18]. Optimization through the assessment of the skin around the ankle for any irregularities, surgical site skin decontamination through alcohol and betadine solutions, surgical site shaving, planning of surgical incision path, and appropriate draping with plastic adhesive, iodine-impregnated drapes should be considered in order to reduce PJI following TAA [18,19]. In addition, implementation of intraoperative measures, such as reducing foot traffic, having an operating room with an efficient ventilation system to reduce aerosolized particles and performing the surgery in an expeditious manner, are all proven to reduce the risk for subsequent SSI/PJI [18, 20–25].

QUESTION 5: What prophylactic antibiotic (type, dose and route of administration) should be administered perioperatively for patients undergoing total ankle arthroplasty (TAA)?

RECOMMENDATION: The administration of prophylactic antibiotics before TAA potentially reduces the incidence of surgical site infection (SSI) and/or periprosthetic joint infection (PJI). Weight-based (of at least 2 gm) Cefazolin administered intravenously within 60 minutes prior to the procedure can be an adequate choice for antibiotic prophylaxis.

If the patient has a beta-lactam anaphylaxis, we recommend an appropriate alternative antibiotic effective against *Staphylococcus*.

It is unclear whether prophylaxis should be given as a single dose or as multiple doses.

LEVEL OF EVIDENCE: Strong

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Published studies report a rate of PJI after TAA that ranges from 2 to 8.6%, exceeding the risk of infection following knee and total hip replacements [1]. Likewise, the incidence of SSI following foot and ankle elective surgeries (2-4.5%) is higher than other orthopaedic procedures [2].

Most expert panels consider it appropriate for antimicrobial prophylaxis to be routinely utilized in surgeries involving prosthetic joints [3–8]. Unfortunately, no high level evidence is available to corroborate its indication specifically in TAA [9,10].

Gram-positive cocci are the most prevalent pathogens in SSI and PJI in foot and ankle surgeries [1,5,11]. Cefazolin is the more widely used antibiotic for standard prophylaxis in orthopaedic surgeries, due to its effective and rapid bone and soft tissue penetration, excellent gram-positive coverage and its long half-life [12,13]. One to 2 grams of Cefazolin administered intravenously is the standard dosage recommended in most guidelines, although some experts suggest increasing the dose to 3 grams if the patient weighs more than 120 kilograms [3,4,7,12]. In patients with a history of severe beta-lactam allergy, who cannot receive cephalosporins, vancomycin or clindamycin are adequate alternatives [3,4,12].

Some studies show reduced SSI rates associated with methicillin-resistant *Staphylococcus aureus* (MRSA) screening and decolonization protocols in elective orthopaedic procedures, but there is no specific data in foot and ankle surgeries or TAA [14,15]. Most experts

recommend performing these procedures on a case-by-case basis, taking into account the history of colonization and the presence of risk factors for MRSA [10,15].

Most guidelines advocate for the administration of prophylactic antibiotics within 60 minutes prior to surgery [3,4,6,7,10]. Studies that assessed patterns of antibiotic bone penetration in prosthetic joint replacements report that effective serum levels of Cefazolin persisted for over eight hours after intravenous administration, achieving peak concentration in bone tissue 40 minutes after the dose [13]. Antibiotic administration 15 minutes prior to incision has not proven to be better than 15-60 minutes before the procedure [2]. Experts advise redosing if procedure time exceeds one to two times the half-life of the antibiotic (1.5-two hours in case of Cefazolin) [3,4,6]. There is conflicting evidence for the need to continue prophylaxis postoperatively, but it is clear that there is no benefit in extending the administration of antibiotics beyond 24 hours after the surgical procedure [4–7,10]. If a proximal tourniquet is used, the antimicrobial should be completely infused before inflation [10,13].

QUESTION 6: What is the optimal management of patients with prior septic arthritis of the ankle who are undergoing total ankle arthroplasty (TAA)?

RECOMMENDATION: There is a paucity of data regarding TAA in patients with prior infection involving the ankle, whether it be septic arthritis, osteomyelitis or infection of the surrounding soft tissues.

We recommend that patients with prior infections in the affected ankle be worked up for infection, including a thorough history and physical examination, as well as ordering serological tests and possible aspiration of the joint. During ankle arthroplasty in patients with prior infection, antibiotics should be added to the cement (if used), and the joint should be thoroughly cleansed. Intraoperative cultures of bone and soft tissue should also be obtained.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

TAA has been used with increasing frequency for the treatment of end-stage arthritis of the ankle. The rate of periprosthetic joint infection (PJI) of the ankle varies in the literature. When it occurs, it can have devastating consequences. There is a paucity of literature regarding the work-up, management and outcomes of PJI in TAA.

With regards to total ankle arthroplasty in patients with a history of infection involving the ankle, only one study in the literature was identified and was a level IV case series. A history of infection in or around the ankle was traditionally seen as a relative, if not absolute, contraindication to TAA [1,2]. However, until 2015, there were no studies on the matter in the foot and ankle literature.

Shi et al. retrospectively identified 22 patients over a 7-year period who underwent TAA who had a history of septic arthritis of the ankle or periarticular osteomyelitis [3]. The preoperative workup for these patients differed based on clinical suspicion and the treating surgeon's preferences. At the very least, all patients had preoperative blood work in the form of a complete blood count (CBC), erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) levels. The decision to perform a preoperative joint aspiration or send intraoperative frozen sections or tissue samples for culture was surgeon-dependent.

At a mean follow-up of 29.3 (range, 11.4 to 83.8) months, there were no PJIs, evidence of radiographic loosening or need for revision of the components. The TAA was performed at an average of 8.8 (range, 0 to 44) years after the diagnosis of infection in or around the ankle. Three patients (14%) had delayed wound healing, and three others (14%) underwent subsequent procedures, which were not for the infection and did not involve revision of any of the ankle arthro-

plasty components. The authors of this study concluded that TAA may be a viable option for patients with a history of infection of the ankle [3].

While this study does demonstrate the potential for infection-free survival of a TAA in patients with a history of infection in or around the ankle, the follow-up of the cohort is too short to allow conclusive recommendations to be made regarding this patient population. Therefore, further studies on the topic are needed. In the interim, we recommend that all patients with infection in or around an ankle that is being considered for TAA be worked up for infection prior to the elective arthroplasty. During the arthroplasty, additional measures should be implemented to reduce the risk of subsequent SSI/PJI.

QUESTION 7: During draping for total ankle arthroplasty (TAA), should the foot be prepped into the surgical field or be covered?

RECOMMENDATION: There is insufficient data demonstrating any advantage or disadvantage to covering the toes during TAA.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Multiple studies have shown increased rates of bacterial colonization in the toes after skin preparation [1–4]. Zacharias et al. reported on the pre-procedural cultures in 12 patients who underwent lower extremity orthopaedic surgery not involving the foot [4]. The authors performed pre-procedural toe cultures, prepared the extremity with povidone-iodine and followed with coverage of the toes with a self-adherent wrap. The authors found a 75% rate of positive pre-procedural and aerobic cultures, concluding that there is some benefit to applying sterile draping to the toes in order to minimize the risk of infection. However, the major weaknesses of the latter study are the small sample size (n = 12), lack of a control group, preparation of the surgical site being done by an operating room nurse not aware of the study and the use of povidone-iodine.

In another study, Brooks et al. demonstrated that there was a significantly lower rate of bacterial recolonization in patients who underwent a standard antiseptic technique in combination with sliding a gauze swab soaked in topical antiseptic multiple times between the toes compared to standard antiseptic technique alone [1].

Hort and DeOrio designed a study that assessed the amount of residual bacterial contamination after surgical preparation of the foot and ankle with or without the use of alcohol [2]. In this study, the 49 patients were randomly assigned to either a standard preparation with chlorhexidine gluconate home scrubs and preoperative povidone-iodine or a standard preoperative preparation with the addition of 70% alcohol. While there was a trend towards significance, the authors found no significant difference in colonization rates with or without the use of alcohol. However, they found high rates of residual colonization (35% in the standard surgical group and 57% in standard preparation plus alcohol). Subsequently, the authors' conclusions included the recommendation of covering the toes during hindfoot and ankle surgery. No patient had any clinical evidence of infection or wound problems. It should be noted, however, that this study did not specifically compare patients with their toes uncovered or covered.

However, despite the presence of studies recommending covering the toes to decrease the risk of contamination in lower extremity surgeries, there are limited studies assessing the rates of infection with the toes covered versus uncovered. Goucher et al. performed a prospective, randomized study to assess the effect of covering the toes during hindfoot and ankle surgery [5]. In this study, they performed three sets of cultures (before skin prep, immediately after skin prep and after the conclusion of the surgery) from the foot and toes from one group of 20 patients with their toes covered and a second group of 20 patients with their toes uncovered. Of 40 patients, only two postoperative cultures were positive, and neither of these patients showed any signs of postoperative infection. Additionally, while seven patients showed signs of superficial infection (erythema, superficial dehiscence or suture abscess), there was no difference between the two groups. Therefore, the authors concluded that there were no benefits in covering the toes in hindfoot and ankle surgery.

Recently, the order of skin preparation has also been investigated. Hunter et al. performed a prospective, randomized control study to assess the proper order of skin preparation of foot and ankle orthopaedic surgeries [6]. The authors found that there were lower rates of positive post-procedural cultures in patients undergoing preparation with isopropyl alcohol followed by chlorhexidine compared to patients undergoing preparation with chlorhexidine followed by isopropyl alcohol. However, no assessment was performed comparing coverage versus non-coverage of the toes during the procedure.

Although inconclusive, there is ample evidence of persistence of bacterial colonization irrespective of skin preparation technique of the foot. Consideration should be given to covering the toes to limit the risk of contamination of the surgical site and the potential for subsequent infection.

QUESTION 8: Should antibiotic-impregnated cement be used during primary total ankle arthroplasty (TAA)?

RECOMMENDATION: Unknown. There is insufficient evidence for the routine use of antibiotic-impregnated cement during primary TAA.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

The main sources for this systematic review were the Medline, Embase, CINAHL and Cochrane CENTRAL databases, beginning with the first citation of ankle arthroplasty in July 2003, the 2016 Swedish Ankle Registry [1] and the 2016 New Zealand Joint Report [2].

In their report on the New Zealand Joint Registry, Rothwell et al. reported on 1,261 TARs from January 2000 to December 2015. Cement fixation was used only in 13 tibial components and in seven talar components. Antibiotic-impregnated cement was used seven times for tibial component fixation and three times for the talus component fixation. However, there was no statistical evaluation in this registry for the item periprosthetic joint infection (PJI) according to the type of cement used.

Considerable research is available related to PJI and antibiotic-impregnated cement for total knee arthroplasty (TKA) procedures. Gutowski et al. stated in their study that the absolute rate of infection increased when antibiotic-loaded cement was used in TKA, although this was less when compared to infection rates after use of plain cement [3]. In 2016, Schiavone et al. performed a systematic review determining the effectiveness of utilizing antimicrobials and the safety of antibiotic-loaded bone cement in primary TKA [4]. The authors concluded that there was no significant difference in the rate of deep or superficial surgical site infection in patients receiving antibiotic-impregnated cement in primary TKA compared with those receiving plain cement.

Based on the lack of proven efficacy for antibiotic-impregnated cement in the prevention of PJI in the TKA literature and the lack of research into antibiotic-impregnated cement in TAA, we cannot provide a recommendation for or against the routine use of antibiotic-impregnated cement during TAA. However, this point may be of limited current importance anyway, as the majority of modern generation TAA are cementless in design.

1.2. PREVENTION: NON-TOTAL ANKLE ARTHROPLASTY-SPECIFIC

Authors: Gaston Slullitel, Yasuhito Tanaka, Ryan Rogero, Valeria Lopez, Eiichiro Iwata, Yusuke Yamamoto

QUESTION 1: What are the benefits and risks associated with the use of vancomycin powder in the wound during total ankle arthroplasty (TAA) or other foot and ankle procedures?

RECOMMENDATION: Though one study supporting topically-applied vancomycin has shown it to reduce the rate of deep infection in diabetic patients undergoing foot and ankle surgery, there is insufficient evidence to show benefits or to show any risks associated with the use of vancomycin powder during TAA or other foot and ankle procedures in a general population.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

The effects of the use of vancomycin powder in foot and ankle surgery are ill-defined. Wukich et al. evaluated the use of vancomycin powder exclusively in foot and ankle procedures, though this was performed in a population composed solely of patients with diabetes mellitus [1]. The authors concluded that odds of surgical site infections (SSIs) (73% decrease) and deep infections (80% decrease) were significantly reduced in diabetic patients who underwent reconstructive surgery of a foot and/or ankle deformity or trauma and received topically-applied vancomycin when compared with a group of patients who did not receive topically-applied vancomycin. The rate of superficial infections did not differ significantly between the two groups. Based on this retrospective controlled study, the authors concluded that foot and ankle surgeons may consider topically applying 500 to 1,000 mg of vancomycin powder prior to skin closure in patients who are not allergic to vancomycin. To our knowledge, no others studies have evaluated the use of vancomycin powder exclusively in foot and ankle surgery.

The effectiveness of vancomycin powder has been documented more extensively in other orthopaedic subspecialties than foot and ankle [2–6]. A systematic literature review by Kanj et al. showed local vancomycin-impregnated cement and powder to be associated with lower infection rates while also being safe and effective in clean orthopaedic surgery [2]. The authors especially recommended utilizing local vancomycin in spine surgery, in which patients without local antibiotic prophylaxis were more than four times more likely to experience a deep postoperative wound infection. Evaniew et al. concluded through their meta-analysis that there is a lack of high-quality evidence to inform the use of intrawound vancomycin in spine surgery [3]. Xie et al. found from their meta-analysis on intrawound vancomycin in spinal surgery that the odds of developing postsurgical wound infection without prophylactic local vancomycin use were 2.83-fold higher than the odds of experiencing wound infection with the use of intrawound vancomycin [4]. Furthermore, a retrospective review performed by Singh et al. that assessed the efficacy of intraoperative vancomycin powder administration on preventing deep SSI in high-energy lower extremity trauma (including tibial plateau fractures and pilon fractures) found that the rate of deep SSI between the groups was not statistically significantly different [7].

Concerns have been raised about the potential risks of the local use of vancomycin, including selection for gram-negative and multi-drug-resistant bacteria, increased local tissue irritation, hypersensitivity or anaphylaxis, impaired renal function, and increased seroma formation [8]. However, these adverse effects are mostly hypothetical and have not been reported in the literature, though a case of circulatory collapse due to topical vancomycin application during spine surgery was identified [9].

Although vancomycin powder appears to be effective at decreasing postoperative infections in spine surgery according to some studies, a large void remains in the evidence for other orthopaedic subspecialties, especially foot and ankle. Randomized controlled trials, particularly within the fields of arthroplasty and trauma, are needed to determine the efficacy of local vancomycin powder for infection reduction. In this scenario, a phase III prospective randomized clinical trial is being conducted among high-risk tibial fracture patients to assess the efficacy of locally administered vancomycin powder in the prevention of SSI after fracture surgery [10], which may bring increased clarity to this matter.

QUESTION 2: Is there a role for the use of dilute povidone-iodine (betadine) irrigation or other antiseptic irrigation solutions during total ankle arthroplasty (TAA) or other foot and ankle procedures?

RECOMMENDATION: With regards to TAA, there is a lack of evidence to recommend for or against the use of betadine solution.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

In 2016, the World Health Organization (WHO) published guidelines for the prevention of surgical site infections (SSIs) [1]. Based upon a review of 17 randomized controlled trials, there is moderate quality evidence that alcohol-based antiseptic solutions for preparation of the surgical site decrease the risk of SSIs in comparison to aqueous solutions. A low quality of evidence showed decreased SSI risk with alcohol-based chlorhexidine gluconate compared to alcohol-based betadine. While alcohol may be concerning for persons from certain religions, the WHO guideline highlights the statement issued in 2002 by the Muslim Scholars Board of the Muslim World League. According to the Board, medicines containing alcohol may be used as an external cleaner. With the use of alcohol-based agents, care must be taken to allow them to dry completely, as operating rooms fires have been reported. According to the Centers for Disease Control and Prevention (CDC), skin preparation with an alcohol-based antiseptic solution should be completed prior to surgery, to reduce the risk of SSI [2].

A systematic review and meta-analysis of combination chlorhexidine gluconate (CHG) and betadine implicated the utility of these agents, despite the low quality of the evidence. A major limitation of many of these studies, however, was the use of bacterial colonization as an endpoint rather than the development of a true SSI [3].

Privitera et al. recently provided a meta-analysis updating and clarifying issues from prior meta-analyses which had not clearly distinguished among studies using alcohol and aqueous-based products. In the updated meta-analysis, there was subgroup analysis showing decreased colonization rates with chlorhexidine, but there was not a statistically significant difference in SSI due to the low numbers of SSI [4].

Although the use of antiseptic agents for skin preparation is necessary for bioburden reduction and prevention of infection, there is minimal data available regarding the role of antiseptic irrigation solutions during TAA. The use of antiseptic agents for irrigation is often performed in the setting of periprosthetic joint infections (PJI) of the hip and the knee, although the utility in total ankle replacements is unknown.

Randomized controlled studies have evaluated the use of various irrigates in open fracture wounds, noting that normal saline was more efficacious and as effective at decreasing infection in comparison to castile soap and bacitracin solution, respectively [5,6]. Chlorhexidine solutions have been evaluated in an in vitro model as being beneficial to decreasing the biofilm load, particularly at concentrations above 2%. However, of importance is that concentrations as low as 0.02% CHG have shown to lead to fibroblast toxicity [7,8]. Dilute betadine may be advantageous in this regard, as it has minimal cellular toxicity at low concentrations and excellent efficacy for prevention of infection [9].

Based on the available data, the CDC has recommended that strong consideration should be given to the use of dilute betadine during all surgical procedures. Although no data in TAA exists, extrapolating the recommendations of the CDC to TAA appears to be reasonable as dilute betadine is inexpensive, efficacious and carries little-to-no cell toxicity.

QUESTION 3: Does revascularization prior to foot and ankle surgery reduce the incidence of surgical site infection (SSI)?

RECOMMENDATION: Several studies support the effect of peripheral vascular disease (PVD) on wound healing and SSI. Despite this, there have been no specific studies proving the beneficial effect of revascularization on SSI prior to surgical intervention in the setting of traumatic or elective foot and ankle surgery. The majority of studies on revascularization are in the setting of diabetic foot infection or established ischemia.

We recommend that in the presence of an inadequate vascularization in the foot and ankle, vascular optimization should be undertaken prior to elective surgery.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Oxygenation of soft tissues is a critical component of wound healing, with wound tissue oxygen tension having a direct correlation with the risk of postoperative wound infection [1].

Diabetes mellitus (DM) and its complications, such as PVD, have proven to be risk factors for increased infection and complication rates after surgery for ankle fractures [2–4]. A large cohort study of

over 57,000 patients found that PVD alone was a strong risk factor for the development of complications after ankle fracture fixation, with the rate of infection increased from 1.44% to 6.87% in the presence of PVD [2].

Diabetes and PVD are associated with increased complications in other forms of foot and ankle surgery, as well [5]. PVD is a proven risk factor for infection after arthrodesis procedures of the foot and ankle and is an independent risk factor for periprosthetic joint infection (PJI) following total ankle arthroplasty [6,7].

Clinical guidelines for the management of diabetic foot disorders suggest a thorough assessment for vascular risk factors prior to surgery [8]. PVD and poor oxygen delivery to tissues are associated with poor wound healing in these patients and should thus be identified [9,10]. Angiography should also be performed when appropriate to assess the potential for revascularization [8], as this intervention has shown to improve the level of amputation and tissue loss in this group of patients [11–13]. Furthermore, Faglia et al. demonstrated revascularization in diabetic patients with critical limb ischemia to lead to a low rate of early amputation [14].

Aust et al. reported that combining revascularization with surgical intervention results in improved wound perfusion and healing of chronic wounds [15]. Revascularization prior to surgery can even allow for successful primary closure of some chronic wounds, according to Barshes et al. [16]. Furthermore, two groups have reported that if primary closure is not viable, then revascularization can be completed in the setting of free tissue for chronic wounds [17,18].

Transmetatarsal amputation can be an effective method of limb salvage in the ischemic or infected diabetic foot, and the rates of wound healing and limb salvage have demonstrated to be improved in conjunction with revascularization [19,20]. Additionally, it is important to understand that the timing of revascularization prior to surgery has not been shown to influence outcomes [21,22]. This would suggest that revascularization prior to diabetic foot surgery is not essential but beneficial when performing revascularization close to foot and ankle surgery in the diabetic patients.

There is little literature related to the effect of revascularization in preventing SSI in foot and ankle surgery. While the presence of PVD is known to increase the risk of SSI/PJI in patients undergoing foot and ankle procedures, no specific study demonstrates revascularization of the foot and ankle obviates this increased risk.

QUESTION 4: Are prophylactic perioperative antibiotics required for isolated forefoot procedures, such as hammertoes?

RECOMMENDATION: Though limited clinical data exists, the administration of perioperative antibiotics is not required for isolated forefoot procedures in the absence of any risk factors, such as immunodeficiency or diabetes mellitus.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 67%, Disagree: 25%, Abstain: 8% (Super Majority, Weak Consensus)

RATIONALE

One high-quality and one moderate-quality prospective randomized control study have demonstrated that there is no significantly different rate of infection in patients who received perioperative antibiotics compared to those who did not receive antibiotics [1,2]. There are also multiple other low-quality studies to support this finding.

A prospective randomized controlled trial of 100 adults undergoing toe fusion with Kirschner wires (K-wires) revealed no significant difference in the infection rate between the group that received prophylactic antibiotics (6.2%) versus the group that did not receive antibiotics (1.9%) [1]. Additionally, a recent multicenter, double-blinded, randomized clinical trial of 500 patients undergoing removal of orthopaedic implants from the lower extremity in the Netherlands showed no significant difference between the group that received a single preoperative dose of intravenous cefazolin (13.2%) when compared to the group that received saline (14.9%) [2].

In their retrospective analysis of 555 patients who underwent elective foot and ankle surgeries, Zgonis et al. reported a 1.9% rate of infection in those who received preoperative antibiotics, compared to a 1.4% rate in patients who did not receive preoperative antibiotics [3]. The authors concluded that prophylactic intravenous antibiotic use in routine elective foot and ankle surgery is not warranted.

Based on a systematic review of the literature, the American College of Foot and Ankle Surgeons has made a recommendation that although there is little to no empiric evidence to support administrating prophylactic antibiotics in elective foot and ankle surgical procedures, antibiotics should be considered [4,5]. They concluded that there is a relative divide between empirical science and common practice. Despite the absence of evidence to support the use of prophylactic antibiotics, it is nevertheless widely used and is a requirement of most hospital systems in order to satisfy quality measures. They justified the practice as being an intervention without significant risk. However, the cost to the healthcare system or the potential for the emergence of resistant organisms was not considered in their 2015 and 2017 statements.

In a survey emailed to all active and candidate members of the American Orthopaedic Foot and Ankle Society, Ruta et al. reported that the majority (75%) of orthopaedic foot and ankle surgeons use prophylactic postoperative oral antibiotics [6]. Most surgeons (69%) prescribed antibiotics to fewer than 25% of patients, although 16% of surgeons prescribed for all elective cases. The finding of the survey was that there was no significant difference in surgical site infection rate among the patients of surgeons who prescribed antibiotics versus those who did not. Another national survey study showed that 25% of attending physicians at foot and ankle fellowships in the United States would administer perioperative antibiotics for foot and surgeries that require K-wire fixation [7].

There is no scientific evidence to support the administration of prophylactic intravenous antibiotics in elective forefoot surgeries. However, even with the lack of high-quality clinical studies, the administration of perioperative antibiotics as a quality measure for most hospital systems and being considered a common practice have led surgeons to administer perioperative antibiotics for forefoot surgeries.

Diagnosis

2.1. DIAGNOSIS: TOTAL ANKLE ARTHROPLASTY-SPECIFIC

Authors: Michael Aynardi, Milena M. Plöger, K.C. Walley, C.B. Arena

QUESTION 1: What is the definition of acute and chronic periprosthetic joint infection (PJI) of total ankle arthroplasty (TAA)?

RECOMMENDATION: There is a paucity of data for defining acute or chronic PJI following TAA in the literature. Any discussion of PJI after ankle replacement is entirely reliant on the literature surrounding knee and hip arthroplasty.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE:

PJI after TAA is an unfortunate and serious complication that bears significant consequences to the patient and impediments to the natural history of ankle replacement, often prompting revision arthroplasty, conversion to arthrodesis or potentially below-the-knee amputation. While the practice of TAA has gained popularity in recent years [1], there is a paucity of data describing wound complications and acute or chronic PJI of TAA. The review of the current literature fails to identify a specific set of accepted criteria for defining an acute or chronic PJI of TAA.

Diagnostic criteria of acute or chronic PJI (non-specific to TAA) is guided by the definition developed by the Musculoskeletal Infection Society, which was later modified in 2013 by the International Consensus Group on Periprosthetic Joint Infection (Table 1) [2]. Diagnosis of PJI requires the presence of one major criterion or presence of at least three of five minor criteria. Acute infections were defined by presentation within 90 days of index surgery and chronic infections after 90 days. Acute and chronic infections each have a different set of threshold levels for the minor criteria (Table 1) [2].

The current literature regarding ankle replacement is significantly limited in data available on PJI. Of the studies that reference diagnosis of PJI in TAA, only one study by Alrashidi et al. offers any explicit reference to a diagnostic algorithm used to classify patients with periprosthetic ankle infections [1]. While not explicitly delineated, the authors appear to invoke laboratory threshold measurements described by the International Consensus Group on Periprosthetic Joint Infection in their proposed diagnostic diagram. Our systematic review failed to identify any clinical study or publication that had implemented or referenced the diagnostic algorithm submitted by Alrashidi et al.

While Alrashidi et al. have presented the most comprehensive and systematic pathway to date specific to diagnosing a PJI in TAA [1], the criterion utilized in this pathway are derived from previously described literature specific to knee and hip arthroplasty [2,3]. TAA data is significantly more limited and thus difficult to establish statistically significant infectious indicators specific to the ankle joint. Alrashidi et al. present clinically useful data in their diagnostic algorithm including the presence of a sinus tract, cell count, and differential from synovial aspiration, culture from synovial aspiration, nuclear imaging studies and histological frozen sections. However, no sensitivities or specificities of the results have been described in determining PJI specific to TAA. Ferrao et al. also described similar work-up in diagnosing PJI in TAA including clinical history, physical examination, radiographic evaluation and laboratory values [4]. Pertinent history, such as sudden onset of pain, swelling, drainage, fever and associated clinical findings, such as tenderness, increased local temperature and effusion, were components concerning for PJI as described by the authors. This study presented a similar diagnostic pathway, including inflammatory markers and joint aspiration, and also made reference to the hip and knee arthroplasty literature in setting criteria and thresholds [5–7]. The trend of referencing hip and knee arthroplasty data in the work-up of PJI in TAA in our systematic review was common in the literature [8–14].

Patton et al. define PJI by positive preoperative or intraoperative cultures or the presence of chronic draining sinus tract, but do not provide reference for this definition [15]. Meyerson et al. similarly defined PJI by draining sinus tract, positive preoperative aspiration (purulent aspirate, positive Gram stain and/or elevated leukocyte count > 1,000 per mm^3) or positive intraoperative culture [16]. The authors subdivided infections into acute and chronic, but did not specify criteria for differentiating between the two. Kessler et al. defined PJI as clinical signs of infection plus at least one of the following: (1) same bacteria grown on two separate preoperative or intraoperative cultures, (2) visible pus surrounding the joint, (3) acute inflammation on histopathological examination (> 10 neutrophils/HPF) or the ability to probe the base of the wound to the implant) [10,11].

Other mentions of PJI in TAA in our literature search did not specifically describe the criteria used to reach that diagnosis [9,17–19]. Case reports of PJI in TAA were also described without defining parameters for diagnosis of acute or chronic infection [20,21]. Further review did demonstrate several manuscripts, which identified risk factors for PJI, including proximity to dental procedures or medical comorbidities but failed to provide a definition for diagnosis of acute or chronic PJI [22,23]. Our systematic review yielded definitions of acute and chronic PJI defined in total hip and knee literature, case

TABLE 1. Diagnostic criteria of periprosthetic joint infection according to the International Consensus Group on Periprosthetic Joint Infection

Major Criteria		
• Identification of 2 positive periprosthetic cultures with phenotypically identical microorganisms OR • Presence of a sinus tract communicating with the joint		
Minor Criteria		
• Elevated serum CRP AND elevated ESR • Elevated synovial fluid WBC count OR ++ change on leukocyte esterase test strip • Elevated synovial fluid PMN% • Positive histologic analysis of periprosthetic tissue • A single positive culture		
Threshold Levels for minor criteria for PJI		
Criterion	**Acute PJI**	**Chronic PJI**
ESR (mm/h)	Not helpful with no defined threshold	30
CRP (mg/L)	100	10
Synovial WBC count (cells/ µl)	10,000	3000
Synovial PMN %	90	80
Leukocyte esterase	+ OR ++	+ OR ++
Histologic analysis of tissue	> 5 neutrophils per HPF (x 400) in 5 HPF	

CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; PMN%, polymorphonuclear neutrophil percentage; WBC, white blood cell count; HPF, high-powered field; PJI, periprosthetic joint infection, mm/h, millimeters per hour; µl, microliters. (Adapted with permission [2].)

reports, as well as suspected risk factors, signs, symptoms and history related to PJI.

In summary, there remains no definitive criterion in the literature for defining acute or chronic PJI after ankle arthroplasty. In the absence of specific diagnostic criteria for PJI of TAA, we may need to rely on the literature related to total hip arthroplasty and total knee arthroplasty to investigate this area further. A recent study published offers an evidence-based and validated definition for PJI of the hip and knee [24]. The criteria based on pretest probability offer each diagnostic criteria a score that is commensurate with the performance of the test in the pre-test probability and diagnostic odds ratio [24].

Authors: Nima Heidari, Irvin Oh, Francesc Malagelada

QUESTION 2: What is the diagnostic "algorithm" for infected total ankle arthroplasty (TAA)?

RECOMMENDATION: Patients who present with clinical symptoms and signs of periprosthetic ankle infection (pain, erythema, warmth, sinus tract, abscess around the wound) and sinus tracts communicating with the ankle/subtalar joint are likely to have TAA infection.

In the absence of a sinus tract, elevated inflammatory markers (erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP)) should prompt ankle joint aspiration for cell count, differential and culture. The joint aspiration is to be repeated.

If the same organism is identified in at least two cultures of synovial fluid, the patient is diagnosed to have an infection. If the repeat aspiration is negative, further investigation is warranted.

In patients not requiring surgical intervention for other reasons, nuclear imaging should be considered for diagnosis. If an operation is indicated, histologic examination (> 5 neutrophils/high-power field) or synovial fluid analysis is conducted to confirm infection.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Diagnosis of infected TAA is mainly guided by the periprosthetic joint infection (PJI) diagnostic criteria developed from the MusculoSkeletal Infection Society (MSIS) and the International Consensus Meeting [1–3]. Although the current PJI diagnostic criteria were developed based on hip and knee patients, the majority of the infected TAA clinical studies have employed the same or a variation of the MSIS criteria [3–9]. The major diagnostic criteria include (1) presence of a sinus tract which communicates with the joint or (2) two positive cultures isolating the same pathogen from the periprosthetic tissue or synovial fluid samples [1–3]. Minor criteria include elevation of inflammatory markers (CRP, ESR), elevated synovial fluid white blood cell (WBC) count or change on leukocyte esterase test strip, elevated synovial fluid polymorphonuclear cells, positive histologic analysis of periprosthetic tissue and single positive culture [1–3]. The above diagnostic algorithm was also recommended by the same authors [1–3].

Systematic literature reviews and meta-analyses have shown a 0 to 4.6% occurrence of deep infection after TAA [10,11]. Myerson et al. reported a 3.1% infection rate after TAA [6]. Their criteria for diagnosis was based on clinical findings of swelling, inflammation, drainage or persistent wound problem which prompted the protocol of joint aspiration for culture and microscopy. Synovial fluid analysis and lab analysis of inflammatory markers (CRP, ESR, WBC count) were tested to confirm infection. Patton et al. utilized similar criteria and reported a 3.2% rate of ankle PJI [7]. Usuelli et al. employed the same diagnostic criteria suggested by the MSIS and reported a 3.7% deep infection rate in the anterior approach group compared to a 1.4% deep infection rate in lateral approach group [9].

However, some authors have raised the possibility that the current MSIS guideline for diagnosis and treatment of hip and knee PJI may be different from the ankle joint, given the relatively thinner soft tissue envelope and limited number of patients who underwent successful joint-preserving revision ankle arthroplasty [3,5]. Moreover, no clinical study has validated utilization of the current hip and knee PJI diagnostic criteria for ankle PJI. Therefore, a high-quality clinical investigation is needed to validate the current criteria and algorithm for diagnosis and treatment of the ankle PJI.

QUESTION 3: What tests are useful to investigate a possible infection of total ankle arthroplasty (TAA)? What are their thresholds?

RECOMMENDATION: Overall, the approach to a potentially infected TAA does not change compared to other periprosthetic joint infections (PJIs). There are no novel or unique diagnostic procedures for TAA infection, specifically. Joint aspiration or intraoperative tissue/synovial biopsies with microbiological cultures are the most important diagnostic tests for suspected TAA infections. In the absence of specific data related to TAA, the threshold for these tests should be derived from the hip and knee PJI literature.

LEVEL OF EVIDENCE: Strong

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

The literature lacks information regarding a specific diagnostic work-up for infected TAA compared to PJI of other joints. Clinically, persistent pain with or without loosening of the components is believed to be a potential presentation for PJI of TAA [1–3]. According to some authors, the pain localization can hint at one diagnosis versus another; anteromedial pain is commonly caused by gutter impingement or medial ankle stress reaction, whereas more diffuse pain is usually associated with stiffness, loosening or infection [3]. A prior history of delayed surgical wound healing is often reported in patients with infection [4]. The presence of a sinus tract is definitive evidence of infection but is infrequently seen [4].

Ankle swelling and pain progressing to incisional discharge then dehiscence and rapid loosening are strongly suggestive of infection. In these cases, a joint aspiration or intraoperative tissue/synovial biopsies and microbiological work-up, remains the preferred method for diagnosis of TAA infections [2–7]. The microbiological techniques (culture, polymerase chain reaction) are not specific for TAA infections. In infected TAA literature that identifies the causative pathogen, there is a trend towards TAA PJI being affected by a higher proportion of gram-positive microorganisms compared to other PJIs and a smaller proportion of gram-negative bacteria [4,5]. Of note, the microbiological evaluation in one study found no single gram-negative bacteria among 19 cases of infected TAA [7]. Intra-articular leukocyte differentiation, leukocyte esterase, intra-articular C-reactive protein, or alpha-defensin immunoassays of prosthetic joint samples have not yet been sufficiently validated for TAA PJI [8]. Other than during the initial work-up to rule out infection, systemic serum inflammatory markers are practically of no additional advantage. Many authors do not dogmatically recommend their use [3]. Likewise, imaging techniques do not prove infection but may show the localization of abscesses or may confirm implant loosening [1]. Hsu et al. suggested that more than 10 leukocytes per high-power microscopic field in the synovial biopsies would be suggestive of infection [1]. Other groups have reported that >5 leukocytes per high power field in frozen section microscopy may be indicative of PJI [5,7]. However, these approaches are not shared with the majority of author groups and convincing data in favor of microscopic leukocyte counting for TAA specifically are lacking.

Ultimately, there is little consensus regarding the work-up for TAA PJI. Many diagnostic tools are used based on provider preference, with only aspiration and fluid analyses being universally endorsed in the literature.

QUESTION 4: What are the indications for aspiration of a possibly infected total ankle arthroplasty (TAA)?

RECOMMENDATION: Whenever a periprosthetic joint infection (PJI) of a TAA is clinically possible or suspected, especially when elevated erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) levels exist, and in correspondence to the literature on PJI in total hip and knee arthroplasties, joint aspiration is indicated.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

We performed a systematic review of the literature regarding the research question found above as recommended: A PubMed Search for the MeSH Terms ("arthrocentesis"[MeSH Terms] OR "arthrocentesis"[All Fields] OR ("joint"[All Fields] AND "aspiration"[All Fields]) OR "joint aspiration"[All Fields]) AND ("arthroplasty, replacement, ankle"[MeSH Terms] OR ("arthroplasty"[All Fields] AND "replacement"[All Fields] AND "ankle"[All Fields]) OR "ankle replacement arthroplasty"[All Fields] OR ("total"[All Fields] AND "ankle"[All Fields] AND "arthroplasty"[All Fields]) OR "total ankle arthroplasty"[All Fields]) was performed on February 16, 2018. A total of n = 10 results were found.

Additionally a PubMed Search for the MeSH Terms ("infection"[MeSH Terms] OR "infection"[All Fields]) AND ("arthroplasty, replacement, ankle"[MeSH Terms] OR ("arthroplasty"[All Fields] AND "replacement"[All Fields] AND "ankle"[All Fields]) OR "ankle replacement arthroplasty"[All Fields] OR ("total"[All Fields] AND "ankle"[All Fields] AND "arthroplasty"[All Fields]) OR "total ankle arthroplasty"[All Fields]) was performed on February 17th, 2018. A total of n = 200 results were found. After exclusion of irrelevant manuscripts or duplicates, only four publications remained that can be considered a "match" regarding a specific answer to the research question.

Investigation of a prosthetic joint for possible infection, including the ankle, commences with detailed history-taking, physical examination and ordering a series of laboratory tests. There is no gold standard for diagnosis of PJI and because of this, we must rely on a combination of diagnostic techniques to reach or refute the diagnosis of PJI. The serum laboratory tests that should be ordered include ESR, CRP and potentially other tests, such as D-dimer levels. If these laboratory tests are elevated or with normal serological tests and high clinical suspicion for infection, the next line of investigation is believed to be joint aspiration.

The synovial fluid obtained, if any, should be sent for analyses that include total white blood cell count, neutrophil count and the percentage of neutrophils, as well as analyses for biomarkers, such as leukocyte esterase and alpha-defensin. The joint aspirate is also cultured to identify the potential infecting pathogen.

Although the algorithm for investigation of PJI in hip and knee arthroplasty has been well studied and the optimal threshold for parameters, such as cell count and neutrophil differential, determined, there is little data related to PJI of TAA. In the absence of such data, we believe that TAA should also be investigated in a similar fashion to hip and knee arthroplasty. In fact, our search determined that most studies related to TAA use the MusculoSkeletal Infection Society criteria and extrapolate data published in total hip and knee arthroplasty literature to TAA [1]. In one study, Alrashidi et al. recommended that aspiration for synovial fluid analysis should be considered if the ESR and CRP are elevated [2]. This has been corroborated by other studies in recent years, confirming the utility of aspiration to help gauge the presence of inflammation or infection around a TAA [3–5].

Author: Rachel Shakked

QUESTION 5: What is the best technique for performing aspiration of patients with total ankle arthroplasty (TAA)?

RECOMMENDATION: In the absence of evidence, we recommend that ankle joint aspiration to evaluate for periprosthetic joint infection (PJI) be performed under sterile conditions via the anteromedial approach. Ultrasound guidance may be used if available but is not necessary to obtain an acceptable synovial fluid sample.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

In the setting of suspected ankle PJI based on preoperative history, physical, laboratory values and imaging modalities, preoperative aspiration can be useful and may reveal an organism in 50 to 60% of cases [1]. Landmark-based aspiration using a sterile technique via an anteromedial approach performed in the office is most commonly performed in order to obtain ankle synovial fluid for analysis. Imaging guidance via computed tomography or ultrasound is not usually necessary since the ankle joint is relatively simple to aspirate [2]. Ultrasound guidance may provide higher accuracy if available based on cadaver studies evaluating injections, which suggested 85% accuracy without ultrasound and 100% accuracy with ultrasound [3,4]. However, another study demonstrated 100% accuracy in ankle joint needle insertion in a cadaver study using palpation technique only [5]. In the setting of infection, there is typically excess fluid resulting in simpler access to the ankle joint for aspiration. Thus, aspiration can be performed without necessarily using ultrasound guidance.

The ankle can be accessed via several approaches. The most common approach is the anteromedial approach, which is just medial to the tibialis anterior tendon at the level of the ankle joint.

No difference was seen between anteromedial or anterolateral approaches in a cadaver study when performed by orthopaedic trainees, and there was an 80% success rate of being intra-articular with both approaches [6].

The risk of bacterial contamination of the joint after aspiration has not been studied. There is some literature discussing septic arthritis after corticosteroid injection. One report indicated an incidence of 0.5% in a population of patients with rheumatoid arthritis on immunosuppressant medication [7]. In the general population, infection after cortisone injection is reported to range between 1 in 3,000 to 1 in 16,000 [8,9]. It is generally thought to be very rare when a basic sterile technique is used.

We recommend that the site of ankle aspiration is wiped with alcohol and then prepared with the use of another antiseptic agent, such as povidone-iodine or chlorhexidine. Although not absolutely necessary, the site of aspiration may be isolated with the use of sterile towels. The aspiration may be performed in the office setting or the operating room suite, depending on the infrastructure in each facility.

QUESTION 6: Should aspiration of the ankle with an antibiotic spacer be performed prior to reimplantation?

RECOMMENDATION: We recommend that aspiration of the ankle with an antibiotic spacer prior to a second-stage reimplantation should be strongly considered. Available studies indicate that a positive culture of the aspirate in this setting is predictive of residual infection, while a negative aspirate culture does not rule out infection and should be interpreted in light of other clinical indicators and laboratory values.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 92%, Disagree: 8%, Abstain: 0% (Super Majority, Strong Consensus)

RATIONALE

There have been no studies in the total ankle arthroplasty (TAA) literature that have evaluated the utility of aspiration of an antibiotic spacer as part of a two-stage revision for infected total ankle arthroplasty. In a review article, Alrashidi et al. stated that reimplantation should only be undertaken once the infection is eradicated as indicated by clinical history and examination, serological testing and synovial fluid aspiration [1]. However, no references or evidence is cited to support this assertion. Two large series on the treatment of infected TAA each included two-stage revision with use of an antibiotic spacer as a treatment strategy [2,3]. However, neither study included preoperative aspiration of the antibiotic spacer in the methodology. Of note, Myerson et al. did routinely perform intraoperative examination of tissue and fluid by microscopy during definitive reconstruction surgery in order to evaluate for the presence of polymorphonuclear (PMN) leukocyte count > 5 per high power field or the presence of organisms on Gram stain [2]. If either criterion was met, repeat debridement with antibiotic cement spacer exchange was performed and the definitive reconstruction was deferred.

There have been numerous studies in the total hip and knee replacement literature investigating the utility of aspiration of antibiotic spacers. While these have provided valuable data, it should be noted that these studies were largely retrospective and non-uniform. The definition of the presence of infection was also not clear in some of these studies, and positive culture was considered by many studies as the gold standard. Some studies also correlated the results of the aspiration and intraoperative findings with the ultimate success or failure following reimplantation. The studies also have significant variability in the duration of antibiotic treatment as well as variability in the presence/absence and duration of an antibiotic holiday.

Studies regarding aspirate cultures of antibiotic spacers for infected total knee arthroplasty reported generally better specificity than sensitivity. Specificity ranged from 61 to 100% while sensitivity ranged from 0 to 83% [4–8]. Positive predictive value ranged from 0 to 100% while negative predictive value ranged from 74 to 97% [4–8]. Aside from cultures, additional aspiration tests have been evaluated for accuracy. There is significant variability across reported cut-off values and sensitivity and specificity rates for white blood cell count and PMN% of preoperative aspirates [9–12].

One argument for routine aspiration of an antibiotic spacer of the hip or knee prior to reimplantation revolves around the relatively low cost, simplicity and low risk of the procedure. However, in the setting of a temporary antibiotic spacer of the ankle, there is no evidence regarding the success rate of attempted aspirations.

One challenge that exists is the interpretation of a dry aspiration. In the hip, consideration has been given to performing a saline

lavage in order to improve the yield of aspiration. Newman et al. reported that saline lavage predictably affected the results of synovial cell counts and their diagnostic utility but has a less substantial effect on culture results [11].

In the absence of concrete evidence, with reliance on the available data from the hip and knee literature and taking into account the simplicity of aspirating an ankle joint, we recommend that aspiration of the ankle with an antibiotic spacer be strongly considered prior to reimplantation. The analysis of the aspirate fluid, if obtained, will provide valuable data that can influence the intended procedure and the ultimate success and failure of reconstruction.

Authors: Khaled Emara, John M. Embil

QUESTION 7: Is there a role for measuring synovial biomarkers for diagnosis of infected total ankle arthroplasty (TAA)?

RECOMMENDATION: Based on the hip and knee arthroplasty literature, measuring synovial biomarkers may play a role in the diagnosis of infected TAA. The diagnosis of periprosthetic joint infection (PJI) in the setting of a TAA can be confirmed with cultures, provided that a plausible pathogen is recovered in the context of a compatible clinical picture. In the absence of a positive culture, synovial biomarker analysis may help in establishing the diagnosis.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 92%, Disagree: 8%, Abstain: 0% (Super Majority, Strong Consensus)

RATIONALE

TAA has emerged as a successful procedure, improving both pain and function in patients with end-stage arthritis of the ankle, with reported rates of infection ranging from 0 to 4.6% [1]. A specific approach does not yet exist for the diagnosis of PJI in TAA. However, the traditional approach for the diagnosis of PJI in other joints involves joint aspiration and sampling of the synovial fluid for analysis involving synovial white blood cell (WBC) count and differential fluid culture, as well as serum WBC count, erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) levels [2,3].

Elevation of several synovial biomarkers has been identified as indicators of potential PJI, including WBC count, percentage of polymorphonuclear cells (PMN%), α-defensin, leukocyte esterase (LE), interleukin IL-1a, IL-1, IL-6, IL-8, IL-10, IL-17, granulocyte colony-stimulating factor (G-CSF), vascular endothelial growth factor (VEGF), CRP, neutrophil elastase 2 (ELA-2), lactoferrin, neutrophil gelatinase-associated lipocalin (NGAL), resistin, thrombospondin and bactericidal/permeability-increasing protein (BPI) [4–6].

Among the previously-mentioned synovial biomarkers, α-defensin is regarded as the most accurate single test for the diagnosis of PJI, with a sensitivity of 97% and a specificity of 96% [5]. Therefore, the accuracy of α-defensin is closest to the 2013 International Consensus Meeting (ICM) criteria for the diagnosis of PJI [6]. Alpha-defensin also appears to provide the most consistent results, regardless of the causative microorganism or its virulence. Its accuracy even remains unaffected in the setting of antibiotic administration to the patient prior to obtaining the synovial fluid sample [4,5,7]. IL-8 has been shown to follow α-defensin in terms of performance, while the accuracy of synovial fluid culture has been shown to have a sensitivity of 62% and specificity of 94% [5]. Synovial fluid leukocyte count (sensitivity of 89% and specificity of 86%) and PMN percentage (sensitivity of 89% and specificity of 86%) both demonstrate accuracy in diagnosing PJI [5,6]. However, they are already part of the six minor criteria for the diagnosis of PJI according to the ICM 2013 definition of PJI [6]. There is great controversy regarding the cutoff point used for the synovial leukocyte count and PMN percentage, which prevents their use as stand-alone diagnostic tests [4,5,8–12].

LE, with a sensitivity of 77% and specificity of 95%, has the advantage of being inexpensive [5,13–16]. However, there is a level of subjectivity present with the interpretation of LE results, in addition to the possibility of the presence of blood in the fluid affecting the results.

The combination of two or more markers to detect PJI has been studied. It has been shown that the combination of synovial fluid α-defensin and CRP provided a sensitivity of 97% and a specificity of 100% in diagnosing PJI [17]. The combined use of synovial CRP and adenosine deaminase (ADA) improves the positive predictive value [18]. A synovial fluid CRP should be included in the synovial fluid analysis and correlated with other lab markers [17].

QUESTION 8: What is the role of molecular techniques for detection of pathogen deoxyribonucleic acid (DNA) (polymerase chain reaction (PCR) or next-generation sequencing) in patients with infected total ankle arthroplasty (TAA)?

RECOMMENDATION: Molecular techniques, particularly next-generation sequencing and the Ibis T5000 technology, have the potential to be used as an important adjunct in the diagnosis of bacterial infection following TAA, although sufficient clinical evidence is lacking.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

The culture of multiple periprosthetic tissue samples is currently considered the gold standard for microbiological diagnosis of periprosthetic joint infections (PJIs) [1]. However, biofilm-associated infections are not easily detected by culture-based methods and are often resistant to conventional antimicrobial therapy. Therefore, it seems imperative to promptly investigate and subsequently integrate molecular diagnostic techniques into the clinical practice for the management of PJI [2].

The most common molecular techniques that have been used to diagnose PJI are both based on PCR: specific PCR and broad-range PCR [3]. Specific PCR targets a single bacterial species (e.g., *Staphylococcus aureus*) or a group of closely-related species (e.g., all staphylococcal species). These are typically considered real-time PCR assays. Specific PCRs can be used in the diagnosis of any targeted pathogen with extreme sensitivity, potentially detecting even a single copy of the target DNA. This approach provides accurate results within hours and has the advantage of singling out any organisms deemed as significant, thereby making contamination easier to control for, as well as making quantification possible [3].

Broad-range PCR, in contrast to specific PCR assays, provides the opportunity to detect DNA from any pathogen rather than a specific preset of expected pathogens. Almost all broad-range PCR techniques utilized in diagnostic microbiology laboratories are based on the gene coding for the small subunit of the bacterial ribosome (16S rDNA). The main limitations of broad-range PCR relate to inherent problems with contamination and sensitivity. Contamination arises from bacterial DNA present in PCR reagents or inadvertently introduced during the collection and handling of the sample, particularly if additional fluids are added to the culture sample during transport or laboratory processing [4]. Unfortunately, these "contaminant" bacteria detected with broad-range PCR are closely related to the microorganisms that cause low-grade

PJI, making the distinction between true-positive versus false-positive PCR results challenging. For these reasons, broad-range PCR has not yet been integrated into the standard routine diagnostic procedure of PJI by most laboratories, but this technique is a valid option to be applied to the diagnosis of synovial fluid or periprosthetic tissue infections [5,6].

Comparing the specific and broad techniques, one study found the sensitivities of specific PCR for detection of *Propionibacterium acnes* and *staphylococcus spp*. in sonication fluid from prosthetic shoulder infections to be 89% and 97%, respectively [7]. In contrast, broad-range PCR of tissue cultures in patients with PJI has previously demonstrated a sensitivity of only 50% [8].

The arrival of high-throughput (next-generation) sequencing techniques has enabled the generation of thousands of individual sequences from a single broad-range PCR [3]. This approach seems to be promising in aiding in surgical site infection and PJI detection, since it provides detailed information on the bacterial population present in prosthetic joint samples [3]. The next-generation technique of pyrosequencing allows for massively parallel, rapid identification of pathogens at a much lower cost per base than the traditional sequencing. The greater breadth and depth of pyrosequencing, in which hundreds of thousands of sequences can be generated in a single run, means that low abundance species have a higher chance of being detected [3].

When comparing molecular and microbiological techniques on PJIs, culture and PCR have shown similar sensitivities (72.6% and 70.4%) and specificities (98.3% and 97.8%) [9,10]. While using a combination of 16S rDNA PCR and lateral flow immunoassay, the 16S recombinant DNA (rDNA) test system provided a diagnostic result within 25 minutes in 97% of all patients. This can be juxtaposed to the microbiological culture of synovial fluid, which achieved a lower sensitivity than that of the 16S rDNA test with 80% [11]. In terms of cost, molecular diagnosis may be a more expensive diagnostic method than bacterial culture with a cost-effectiveness that has not yet been evaluated [12]. The direct detection of bacterial 16S rDNA shows encouraging results and warrants further evaluation in larger patient cohorts [11].

While molecular techniques have shown to be important in diagnosing PJI in orthopaedic fields other than foot and ankle, they have not been well-studied in the setting of an infected TAA. In one of the few studies identified studying the utilization of molecular techniques in the foot and ankle, Stoodley et al. evaluated several techniques to ascertain the presence of a bacterial infection in an explanted TAA that had an initial negative culture. The techniques included the Ibis T5000, real time-polymerase chain reaction (RT-PCR), a direct culture of the ankle hardware, confocal microscopy, and fluorescent in situ hybridization (FISH) [13].

The Ibis T5000, a research use only (RUO) technology based on the combination of PCR amplification of highly conserved pathogen genomes with high-performance electrospray ionization mass spectrometry and base-composition analysis, is able to tease out a variety of organisms (including bacterial and viral) down to the species level [14]. Data points include number of genome copies, relative organism abundance and antibiotic sensitivity [15,16]. Based on Ibis testing, Stoodley et al. were able to identify the presence of *S. aureus*, *S. epidermidis* and the methicillin-resistant *mecA* gene in tissue on the removed TAA hardware [13]. Additionally, the Ibis detected that there was close to ten times more *S. aureus* in comparison to the *S. epidermidis*. Of all the techniques investigated, the authors proposed the Ibis T5000 technology to have the most potential in aiding with clinical detection of PJI with TAA [13].

In addition to the Ibis system, the authors used RT-PCR in order to detect metabolically active *S. aureus* [13]. The authors were able to harvest ribonucleic acid (RNA) from a tissue sample and after converting the RNA to complementary DNA via reverse transcription, they utilized specific PCR primers for the bacterial glyceraldehyde-3-phosphate dehydrogenase (GAPDH) and histidine ammonia-lyase (*hutH*) genes [17–19]. The study demonstrated the presence of *S. aureus* messenger RNA for both the GAPDH and the *hutH* genes [13].

Another technique was a direct culture of the tibial metal component of the removed ankle hardware. After a detailed agar preparation protocol, the tibial component was placed in a beaker in which an agar formed. After incubation, the number of bacterial colony-forming units (CFUs) on the agar was eventually estimated. The authors reported approximately 1000 CFUs spread across the entire tibial component and composed of methicillin-resistant *Staphylococcus aureus* (MRSA) and methicillin-resistant *S. epidermis* [13].

Confocal microscopy was also implemented for viability determination after staining and using a 488nm excitation wavelength to identify bacteria as living or dead. Fluorescent in situ hybridization (FISH) was also utilized using fluorophore-labeled 16S rDNA sequences specific for *S. aureus* [20–22]. A red Syto59 fluorescent nucleic acid stain was used to stain all bacterial and host nuclei, allowing *S. aureus* to be the only species stained both red and green. Bacteria that were stained with Syto59 solely were distinguished from host nuclei on the basis of size [22,23]. Confocal microscopy and FISH demonstrated a scattered distribution of biofilm formation, with clusters of bacterial colonies on tissue, the talar component edges, the polyethylene bearing surface and the tibial component. FISH testing also indicated that bacterial growth was predominantly *S. aureus* and *S. epidermidis* to a lesser extent [13].

These findings presented by Stoodley et al. offer to be an important diagnostic step to gauge the presence of a bacterial infected TAA [13]. However, further research is necessary to decide the true clinical utility of these techniques.

QUESTION 9: Should culture samples be taken during all revision total ankle arthroplasty (TAA)?

RECOMMENDATION: We recommend that intraoperative cultures be taken during revision TAA. The result of intraoperative cultures should be interpreted together with clinical suspicion for infection and the results of the laboratory and imaging investigations. We also recommend that multiple tissue specimens be collected. Given a lack of evidence for routine intraoperative cultures for revision TAA literature, this recommendation is based on analogous evidence in the total hip and knee replacement literature.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

There have been no studies in the TAA literature that have evaluated the utility of routine intraoperative cultures for all revision TAA cases. Multiple case series and review articles on revision TAA have been published which do not specifically advocate for or against this practice [1–4]. Jonck et al. do, however, recommend curettage of any encountered cysts at the time of revision and advise that cyst material should be sent for cell count, microbial culture and histopathology [3]. However, no data is included regarding previous results and utility of these samples.

There have been multiple studies in the total hip and knee replacement literature investigating the role of routine cultures taken during revision arthroplasty for presumed aseptic failure. Barrack et al. published on a series of revision total knee replacements with unexpected positive intraoperative cultures [5]. There were 41 cases with positive cultures out of 692 total cases. Twenty-nine of these cases had only one positive culture without additional evidence of infection and were considered false positives. None of the presumed false positives had long-term signs of infection or required additional surgery. The other 12 cases had multiple positive cultures or one positive culture and an abnormal preoperative inflammatory marker or synovial aspirate. These cases were treated with a four to six week course of antibiotics and two of these patients presented with early recurrent infection requiring a two-stage exchange. An additional patient had aseptic loosening requiring revision at six years, at which time there was no sign of infection and negative intraoperative cultures. The authors recommended routinely sending at least five sets of cultures in the setting of abnormal preoperative inflammatory markers, abnormal synovial aspirate or tissue appearing concerning for infection intraoperatively at the time of revision.

Jacobs et al. reported on 679 cases of revision hip or knee arthroplasty for presumed aseptic failure [6]. Infection was defined by the presence of two or more positive intraoperative cultures with the same organism. The incidence of unsuspected infection was 10%. For total knee replacements, patients diagnosed with infection went on to require repeat revision for recurrent infection at a higher rate compared with patients who were not diagnosed with infection at initial revision. For total hip replacements, there was no significant increased rate of recurrent infection requiring revision. The authors emphasized the importance of improved preoperative work-up prior to revision total joint arthroplasty to minimize the number of unsuspected prosthetic joint infections.

Given that there is a small but significant incidence of unsuspected joint infection in hip and knee arthroplasty, there is likely a similar incidence of unsuspected TAA infection amongst presumed aseptic failures. Routine cultures at the time of revision for aseptic failure may help to identify unsuspected infections. However, even the literature for hip and knee replacement does not provide significant evidence to suggest how to intervene once the diagnosis is made and whether long-term outcomes can be improved once intraoperative cultures lead to the diagnosis of periprosthetic joint infection (PJI).

Therefore, we recommend that all patients undergoing revision ankle arthroplasty be investigated for PJI, which includes measuring serum markers, aspiration of the joint, intraoperative evaluation (which may include histology) and any other necessary tests. The

result of intraoperative culture during revision ankle arthroplasty can then be interpreted in light of laboratory and imaging investigations and any clinical suspicion for infection.

RATIONALE

Our search of the literature did not reveal any data regarding the optimal number of culture samples that should be taken during foot and ankle surgery. However, there is high-level evidence in the periprosthetic joint infection (PJI) literature regarding this topic. Bémer et al. conducted a prospective multicenter study evaluating the minimum number of samples required to make an accurate diagnosis of PJI [1]. They determined that four samples were sufficient for diagnosing PJI with the highest mean percentage of agreement (98.1% and 99.7%, respectively) in regards to the bacteriological criterion and diagnosis of confirmed PJI.

Atkins et al. performed a prospective study assessing the effect of sample number on the ability to diagnosis PJI [2]. Their study recommended sending five to six specimens and defined a cutoff of three or more positive operative cultures yielding an indistinguishable organism for definite diagnosis. This recommendation achieves an extremely high specificity, but an impractical sensitivity (it would require too many samples). In order to achieve both excellent sensitivity and specificity, five to six specimens with two or more culture-positive samples are recommended to diagnose infection.

The Infectious Diseases Society of America guidelines [3] provide moderate evidence from more than one well-designed clinical trial, without randomization (B-II evidence) recommending at least three (and optimally five or six) intraoperative tissue samples be submitted for aerobic and anaerobic culture to diagnose a PJI.

The majority of studies related to this subject in regards to the foot and ankle relate to the management of patients with diabetic foot ulcer and osteomyelitis. The available studies have revealed that the yield of culture is dependent on how these culture samples are taken (e.g., swab, bone biopsy and so on) and did not evaluate the influence of the number of culture samples taken.

In 144 diabetic foot ulcer patients with suspected osteomyelitis, ulcer swab and bone biopsy specimens were taken. The authors found that there is poor reliability of the ulcer swab culture in identifying the pathogens causing osteomyelitis in this patient population. When used in conjunction with bone biopsy specimen culture, there may be a more reliable isolate for effective management [4]. Another study reported that swab cultures may have utility for guiding the antibiotic selection for management of low-grade infection. In the setting of higher grade infections, deeper tissue culture and biopsy are necessary [5].

Although there is limited literature guiding the number of samples necessary to obtain for foot and ankle infections, this indicates the need for research in this area. Given the extent of studies conducted in other areas of orthopaedic surgery, similar studies should be conducted in the foot and ankle area to better guide appropriate management.

QUESTION 2: What strategies can be implemented to help isolate the causative organism in patients with infection of the foot and ankle?

RECOMMENDATION: Transfer of synovial aspirate in blood culture bottles, obtaining deep biopsy of tissues and bone, obtaining multiple samples, increasing incubation period of cultures and the use of molecular techniques for culture negative cases are some of the strategies that can help improve the ability to isolate the causative organism(s) in infections of foot and ankle.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Given the risk of false positive cultures, it is important to holistically evaluate patients who are suspected to have an infection of the foot and ankle following an algorithm suggested by the Musculoskeletal Infection Society's definition of periprosthetic joint infection (PJI) [1]. It should be noted that these diagnostic criteria have not been evaluated for infections of the foot and ankle. Isolation of the causative organism in orthopaedic infections can be challenging. Culture-negative infections in hip and knee arthroplasty are not uncommon. Using the experience gained from hip and knee arthroplasty surgery and relying on the literature from the same field of orthopaedics, the following strategies may be implemented to improve the yield of culture in foot and ankle infections.

Synovial Aspirate

Synovial aspiration provides a variety of opportunities for testing, including synovial leukocyte esterase (LE) testing, synovial fluid white blood cell (WBC) count and polymorphonuclear (PMN) percentage, alpha-defensin levels, and Gram stain and cultures. In the hip and knee literature, application of synovial fluid to a simple urine test strip evaluating leukocyte esterase levels can be an accurate marker of PJI (sensitivity of 81-93%, and specificity of 87-100%) [2–4]. False positives do occur, and a positive LE strip should not be used in isolation to diagnose PJI. Although specific levels of synovial fluid WBC count and PMN percentage have been reported for diagnosis of PJI in the hip and knee, there is no literature specific to the foot and ankle [5–10]. Although alpha-defensin has been evaluated and is a promising new serologic test in the hip and knee, there is no literature to support its utility in evaluating infections of the foot and ankle [11,12]. While there is currently no literature defining criteria concerning LE, synovial fluid WBC and PMN percentage, or alpha-defensin levels for acute or chronic infection in the native or prosthetic ankle or soft tissue of the foot and ankle, we must use clinical suspicion and abnormal levels established by the adult hip and knee PJI literature until further studies evaluate abnormal levels in the foot and ankle. Several studies have demonstrated low sensitivity with Gram stain testing and poor utility for the diagnosis of PJI [13–15]. However, Gram stain and culture may provide additional information concerning likely causative organism and may help corroborate culture results with Gram stain findings in instances of potential contamination. There is no literature concerning the utility of Gram stain testing in the infected foot or hindfoot, and further studies may be necessary to better understand whether Gram stains aid in the diagnosis or treatment of suspected ankle or hindfoot native infection or PJI.

Blood Culture

Given the role of medical management in PJI with sepsis or bacteremia as well as prognosis, we recommend routine blood cultures for patients with systemic manifestations of infection. Although bacteremia is acknowledged as an etiology of PJI, the role of blood cultures in the diagnosis of PJI remains unknown. Currently, most guidelines state that blood cultures can be considered in light of systemic manifestations of infection but are not routinely obtained [16,17].

However, the care of patients diagnosed with PJI involves a multidisciplinary team, including infectious disease, internal medicine, emergency medicine and critical care physicians. Blood cultures are a staple in the work-up of many other medical conditions and may be acquired by the treating surgeon or more often a collaborating physician. Klement et al. investigated the role that blood cultures play in PJI patients and what association a positive result has on treatment outcome [18]. Blood cultures were obtained from 53.1% of patients (170/320) presenting with PJI at the time of diagnosis, with the same organism being identified 86.0% of the time in both blood and operative cultures. Furthermore, patients with positive blood cultures demonstrated a decreased treatment success rate compared with those with negative blood cultures. Therefore, the presence of positive blood cultures at the time of PJI diagnosis may not only impact the medical management of patients but also serve as a prognosticator towards the likelihood for success.

Tissue vs. Swab Culture

We strongly recommend against the routine use of swabs for surgical culture. In a study of 156 aseptic and septic hip and knee revision arthroplasties, Aggarwal et al. demonstrated that tissue cultures were positive in a higher percentage of septic cases than swab cultures: 28 of 30 (93%) versus 21 of 30 (70%). Surprisingly, tissue cultures were positive in two of 87 aseptic cases (2%), while swab cultures were positive in 10 of 87 (12%) [4]. Tissue cultures demonstrated higher sensitivity, specificity, positive predictive value, and negative predictive value for diagnosing PJI than swab cultures, while swab cultures had more false-negative and false-positive results than tissue cultures [4]. Because swab cultures pose a greater risk of failing to identify or incorrectly identifying causative organisms in PJI, we believe the use of swab cultures in obtaining intraoperative culture specimens should be discouraged.

Number of Intraoperative Samples

We recommend obtaining multiple intraoperative tissue samples for culture in suspected PJI cases or infections of the foot and ankle. Historic hip and knee protocols for periprosthetic tissue collection have been established with a target of five samples [19–21].

However, sensitivity and specificity are maximized with five to six periprosthetic samples being collected [13]. Given the relative difference in the surgical field area in hip and knee versus foot and ankle procedures, culture specificity and soft tissue preservation should not be compromised by taking more than six samples.

Holding Preoperative Antibiotics

We recommend routine holding of perioperative prophylactic antibiotics in all cases with a high suspicion for PJI in which a causative organism has not been isolated. There is mixed literature related to whether routinely holding antibiotics prior to surgery is necessary with no literature specific to foot and ankle. Recent antibiotic administration has been shown to decrease tissue culture sensitivity [22]. However, two prospective (one randomized) studies have demonstrated that prophylactic preoperative antibiotics do not impair the sensitivity of traditional intraoperative cultures [23,24]. Therefore, mandatory withholding of prophylactic antibiotics is not justified in cases where the pathogen has already been isolated preoperatively. Special consideration should be taken into account in cases in which PJI is diagnosed or suspected, but a pathogen has not been identified. In these cases, the use of prophylactic antibiotics is dependent upon clinical judgment.

Frozen Section

Intraoperative frozen section (FS) histopathology should be considered a valuable adjunct to the diagnostic work-up for patients undergoing revision arthroplasty in culture-negative PJI when the potential for infection remains following a thorough preoperative evaluation, but limitations should be noted. An intraoperative FS looking for acute inflammatory neutrophils in tissue obtained from the joint capsule or periprosthetic membrane has been used for intraoperative decision making. Although multiple studies have demonstrated that intraoperative FS of periprosthetic tissues performs well in culture-positive PJI with relatively high specificity, FSs lack the ability to isolate the organism and consistently demonstrated poor sensitivity and ability to rule out this diagnosis [25–29]. The optimum diagnostic threshold (number of PMNs per high-power field (HPF)) required to distinguish PJI from aseptic failure ranges from 5 to 23 with no clear threshold [30–32]. Although the appropriate thresholds for diagnosing PJI in histological analysis is controversial, a maximum tissue concentration between 5 to 10 PMN/HPF in each of 5 or more HPF seems to carry the best diagnostic performance. Neutrophils entrapped in superficial fibrin are not predictive of infection and submitting samples obtained by sharp dissection instead of cautery will help limit false positive diagnoses due to thermal artifacts.

Atypical Cultures – Acid Fast Bacilli (AFB) and Fungal

Mycobacterium and fungi are rare causes of PJI [33–35]. We recommend against routine AFB and fungal testing in suspected septic or aseptic failure except when warranted by patients who are at risk for such infections or when other traditional pathogens have not been identified where clinical suspicion remains elevated. Evidence has demonstrated that routine AFB and fungal testing in presumed aseptic cases does not yield clinically important results nor is it cost-effective [36]. However, when mycobacterium and fungal organisms are considered, AFB and fungal-selective media must be included, and it should be noted that prolonged culture may be required according to national laboratory standards. One should expand diagnostic testing to include tissue samples for histological examination, especially in patients with high clinical suspicions of infection. Resistance of Candida species to fluconazole has been reported in the literature, and susceptibility testing may be requested when resistance to fluconazole is suspected based on isolated species. Antifungal susceptibility testing remains less well developed and utilized than antibacterial testing.

Culture Incubation Period

We recommend that routine cultures be maintained for 5 to 14 days. If PJI by low virulence organisms is suspected, preoperative cultures failed to demonstrate bacterial growth, or if the clinical picture is consistent with culture-negative PJI, the cultures should be maintained for at least 14 days. Evidence demonstrates that extending periprosthetic cultures to two weeks significantly increases culture sensitivity while not increasing the risk of contaminants [21,37–39]. However, we recommend holding cultures for only five days in patients in whom the causative organism has been isolated preoperatively.

Routine Sonication of the Prosthesis or Implants

We are unable to recommend for or against the routine utilization of sonication of explants. The consideration of its use should be limited to cases with high suspicion for PJI or proven PJI cases in which preoperative aspiration fails to yield positive culture. Explant sonication utilizes ultrasonic energy to a fluid immersed sample to dislodge bacteria embedded in biofilm and has been shown to increase the likelihood of isolating pathogens without increasing the risk of contaminants [40–46]. Several studies have demonstrated better efficacy in dislodging bacteria from biofilm on titanium or stainless steel implants and improved sensitivity of cultured samples compared to scraping with a surgical blade [42]. In the hip and knee arthroplasty literature, Trampuz et al. demonstrated that sonication increases the rate of positive cultures and the sensitivity of sonicated fluid to identify that a causative organism was superior to that of tissue culture (78.5 vs. 60.8%) [40]. Similarly, Holinka et al. and Shen et al. found sonicate fluid to have a sensitivity greater than tissue (83.3 vs. 72.2%) as well as synovial fluid (88 vs. 64%), respectively [47,48]. When comparing sensitivities of cultures from sonicated fluid versus tissue samples, Yano et al. identified a sensitivity of 90.4 vs. 56.8%, respectively, in a large cohort of 180 fracture fixation explants [49]. In a mixed cohort of explanted joint prostheses and fracture fixation explants, Portillo et al. demonstrated improved sensitivity of cultures with 100 vs. 87 vs. 59% following inoculation of sonicated fluid in blood culture bottle compared to regular culture of sonicated fluid and tissue cultures, respectively [50]. The sonication of explants is an expensive procedure that is likely not justified in most assumed aseptic cases. In a large prospective study, the greatest benefit of explant sonication over standard tissue culture was found when antibiotics were provided within two weeks of surgery [41]. Although early literature is promising with possible greater sensitivity and improved bacteria detection with sonication, more literature is necessary to demonstrate the clinical efficacy and relevance prior to supporting broad utilization in the foot and ankle.

Fluorescence In-situ Hybridization (FISH)

We recommend against the routine use of FISH in order to evaluate for suspected infection of the foot and ankle. This process utilizes fluorescent probes to stain bacterial ribosomal ribonucleic acid, thus allowing direct visualization of the organisms in a native biofilm. Although FISH techniques have proven to be a highly reliable nonculture method to demonstrate the presence of pathogens even in the presence of biofilm, this technique is limited by its inability to provide speciation or antimicrobial susceptibility testing on the identified organisms [51,52].

Polymerase Chain Reaction (PCR)

We recommend against the routine use of nucleic acid-based testing for diagnostic testing for infection of the foot and ankle. In limited cases with high clinical suspicion of infection but negative cultures, PCR may help identify the unknown pathogens or antibiotic sensitivity. Although PCR techniques have proven to be more sensitive than traditional techniques, the number of false-positive results, as well as cost and availability of this technology, preclude routine screening. PCR should be reserved for limited cases with high clinical suspicion but negative cultures [53,54].

QUESTION 3: What is the optimal method to perform bone biopsy (method, location, imaging use) for patients with foot and ankle infections?

RECOMMENDATION: A bone biopsy should generally be performed in a percutaneous fashion, particularly in cases where surgical debridement is not considered necessary.

If surgical debridement is considered necessary, then an open biopsy can be performed as part of the debridement.

Percutaneous biopsy should be performed under sterile conditions by an interventional radiologist or other physician trained in image-guided techniques.

The location of the biopsy will depend upon the clinical and radiographic evaluations, with a goal of maximizing the yield of the biopsy while minimizing the risk of injury to surrounding and/or overlying soft tissue structures.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Infection in the foot and ankle bone or soft tissues can be associated with significant morbidity and even mortality. Prompt diagnosis and treatment are paramount. Often, diagnosis can be made based on a combination of clinical examination, radiographic imaging and laboratory data. Bone biopsy is considered the gold standard for the diagnosis of osteomyelitis [1–5].

Bone biopsy can be particularly helpful when the clinical exam, radiographic imaging and laboratory data are not clearly confirmatory of an underlying infection. Additionally, a bone biopsy can allow for identification of the infecting organism(s), and therefore allow for a more tailored treatment regimen. It can also exclude rarer causes of bone disease, such as malignancy or osteonecrosis [6,7].

A percutaneous bone biopsy is generally preferable to an open biopsy, particularly in cases where surgical debridement is not considered necessary. Percutaneous techniques are less invasive, less costly and are associated with less morbidity [7–10]. A percutaneous bone biopsy should be carried out under image guidance, generally either fluoroscopy or computed tomography (CT) and should be performed by an interventional radiologist or other physician trained on image-guided techniques. Image guidance allows for specimens to be obtained from specific targeted areas. The choice of imaging technique used to guide the biopsy depends on the anatomic location, availability and practitioner preference. Fluoroscopy can be used for more superficial lesions and allows for real-time guidance. Its main limitation is its two-dimensional nature. CT guidance provides visualization of not only osseous structures but also important soft tissue structures, such as neurovascular structures, within a three-dimensional framework. Its main limitation is the increased radiation exposure in comparison to fluoroscopy. There are reports in the literature regarding magnetic resonance (MR) guided percutaneous bone biopsies, but the availability of MRI-compatible instruments and accessories limits its use [11,12].

The choice of anatomical region to perform a biopsy will depend on the state of the overlying soft tissues and the radiographic findings. The goal should be to increase the yield of the biopsy while minimizing potential risk to nearby soft tissue structures. In general, more superficial areas of concern are targeted. If multiple areas of concern exist, one will also want to prioritize the site which is likely to provide the highest diagnostic yield. The procedure should be performed under sterile conditions to reduce the risk of contamination of skin flora. If possible, multiple samples should be obtained utilizing multiple trajectories within the bone to increase the diagnostic yield of the procedure.

QUESTION 4: What is the best method to differentiate acute Charcot foot from acute infection?

RECOMMENDATION: Differentiation between acute Charcot neuroarthropathy (CN) and acute infection/osteomyelitis is complex and requires multiple (>1) diagnostic criteria. These criteria include an emphasis on the presence of neuropathy, history and physical examination. The absence of skin wounds and resolution of swelling/erythema with elevation makes the likelihood of infection very low.

In unclear cases, laboratory testing, histological examination and culturing of bone specimens, scintigraphy, and imaging, especially magnetic resonance imaging (MRI), may be of benefit.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

At initial presentation, acute infection comprising of cellulitis and osteomyelitis (OM) and CN may be difficult to differentiate. However, it is important for the clinician to make an accurate diagnosis, as correct treatment largely determines outcome as both present a substantial risk of limb amputation and mortality.

Physical features can provide essential clues to the diagnosis. The "probe-to-bone" test, which tests whether the underlying bone is palpable via a probe inserted into a wound, has demonstrated sensitivity ranging from 38 to 95%, specificity ranging from 84 to 98%, and a positive predictive value ranging from 53 to 97% for the diagnosis of osteomyelitis [1–6]. In their study of 1,666 consecutive diabetic patients, Lavery et al. demonstrated that a positive probe-to-bone test increases the probability of OM greater than 50%, whereas a negative test is a strong predictor of absence of infection [3]. The test, however, has shown to have a high variability when performed by inexperienced clinicians, but this intra-observer variability was demonstrated to decline with experience [7].

In terms of other physical features, CN typically affects the midfoot and lacks associated skin breakage, whereas OM is more frequently found in the forefoot and is often accompanied by soft tissue infection or ulcer [8,9]. Additionally, while it is possible to contract OM through hematogenous spread, the vast majority of cases are spread directly via a soft tissue infection or ulcer. A wound size > 4.5 cm^2 is associated with a three times higher chance of underlying OM [10]. However, others have suggested that both ulcers of size > 2 cm^2 and depth > 3 mm are also significant [11,12]. White blood cell (WBC) counts, C-reactive protein (CRP), and erythrocyte sedimentation rate (ESR) are often utilized for work-up of infection. Some investigators have concluded that elevated ESR (> 70 mm/h) is strongly associated with OM [11–14].

A further benefit of ESR is that, while levels of the other inflammatory markers drop rapidly once antimicrobial treatment begins, ESR remains elevated for longer periods of time, therefore making it useful in monitoring treatment efficacy. Interleukin (IL)-6 has also been suggested as a marker for diagnosis of OM and monitoring treatment in preliminary studies [15,16]. However, these inflammatory markers are nonspecific and may be elevated by various other factors. Given that many patients with histologically proven OM may present with a normal WBC count, hematologic studies alone are not reliable for diagnosis of OM [11–14].

Bone culture alone is reported to have a sensitivity of 92% and a specificity of 60% in diagnosing OM in diabetic feet [17]. Bone samples can be obtained by percutaneous biopsy or during surgery [12,18]. However, bone specimens may often yield false-positive or false-negative results. Histologic analysis is suggested to be important in preventing these undesirable results, as several studies have shown that 40 to 60% of histologically proven cases of OM at surgery or biopsies of foot and ankle had negative cultures [19–22]. Therefore, standard criteria for the diagnosis of OM should be a positive culture with histopathologic evidence of infection in bone specimen [23].

Radiographic signs of infection, such as demineralization, periosteal reaction and cortical destruction, may not appear until two to three weeks after onset and require a loss of 40 to 50% bone mass to detect the difference [8,24]. The accuracy of plain radiography for early diagnosis is 50 to 60% with a sensitivity of 60% and a specificity of 80% [25,26]. Therefore, more advanced imaging is needed for diagnosis of acute osteomyelitis.

Magnetic resonance imaging (MRI) is suggested to be an effective modality to aid in early diagnosis [27,28]. A previous meta-analysis has shown that the sensitivity of MRI to diagnose OM in the foot and ankle is 90% sensitive and 79% specific [29]. In a meta-analysis of 16 studies, MRI performance was superior to that of technetium ^{99m}Tc bone scanning, plain radiography, and WBC studies. The sensitivity for the diagnosis of OM was found to be 90% while specificity was 85% [30]. MRI was better able to identify the extent of the involved area, whereas WBC bone scan may have better performance in differentiating OM from CN, especially in patients with metal implants [23,24].

While chronic CN shows low intensity in both T1- and T2-weighted images, both acute OM and acute CN show low signal on T1-weighted images and hyperintensity on T2-weighted images with contrast enhancement. However, these are common markers in both infective and neuropathic disease, making differentiation

of the two difficult [31]. OM almost always follows surrounding soft tissue infection, therefore identifying soft tissue edema, ulceration, or sinus tracts on imaging would suggest infection. MRI findings of diffuse bony edema in bony prominences (calcaneus, metatarsal heads, malleoli) and phalanges, with a contiguous spread would also suggest OM [32–34]. CN typically shows periarticular and subchondral changes (including fractures) as the pathology centers around the joint [35]. Disease affecting one or multiple joints, in particular of the midfoot, would also suggest CN [35].

Aside from MRI imaging, three-phase bone scintigraphy has a high sensitivity (80 to 100%) but poor specificity (25 to 60%) in diagnosing OM [36]. Labeled leukocyte scans (tagged WBC scans) are similarly sensitive, but more specific [23]. Capriotti et al. reported 86% sensitivity and 85% specificity for ^{99m}Tc-labelled leukocyte scintigraphy [37] and Dinh et al. reported that a ^{111}in-labelled leukocyte scan had a sensitivity of 74% and specificity of 68% [29]. Fluorodeoxyglucose (FDG) positron emission tomography (PET), which measures increased intracellular glucose metabolism, has demonstrated promise in diagnosing CN, particularly with regards to negative predictive value. Basu et al. found sensitivity and specificity of FDG PET in the diagnosis of CN to be 100% and 93.8%, both higher than the corresponding values of 76.9% and 75% for MRI [38]. Study results are inconclusive, however, with some authors finding that its use is limited when compared to MRI and WBC scintigraphy [39,40]. Further interesting developments in aiding in diagnosis are PET-computed tomography (CT) and PET-magnetic resonance (MR), which show promising early results [41–43]. Rastogi et al. reported the sensitivity and specificity of FDG PET-CT to be 83.3% and 100%, compared with 83.3% and 63.6% for contrast-enhanced MRI for the diagnosis of diabetic foot OM in the background of CN [41].

Previous systemic reviews of the literature (including the International Working Group on the Diabetic Foot's consensus scheme for the diagnosis of diabetic foot OM) and meta-analyses have proposed specific criteria for differentiation of CN from OM [21,23]. The proposal was based on using post-test probabilities to define broad levels of diagnostic certainty, with OM most likely being present if (1) a bone sample shows positive culture and is confirmed with histopathology, (2) intraoperative finding shows purulence in the bone, (3) intraosseous abscess is found on MRI or (4) exposed bone exists in the foot ulcer with corresponding changes in advanced imaging. However, the validity of the criteria has not been clinically tested and should, therefore, be utilized with caution.

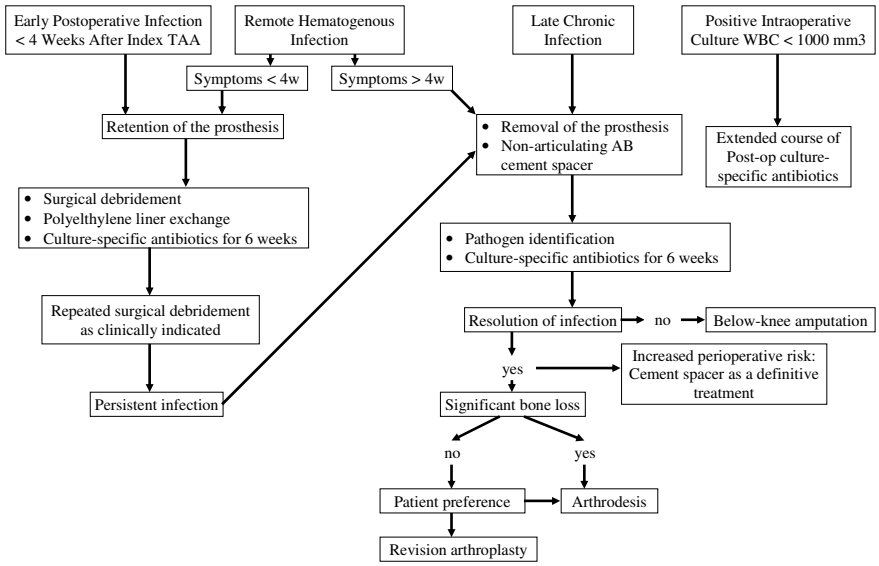
Treatment

3.1. TREATMENT: TOTAL ANKLE ARTHROPLASTY-SPECIFIC

Authors: Steven Raikin, Selene Parekh, Elizabeth McDonald

QUESTION 1: What is the treatment "algorithm" for an infected total ankle arthroplasty (TAA)?

RECOMMENDATION: The treatment of an infected TAA is largely dictated by the acuity of the infection. The following treatment algorithm modified for TAA is recommended [1].



LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

The reported rate of infection after TAA is between 0 to 5% [2–4]. The management options are based on the time of presentation after index TAA and the duration of infection symptoms. It is a common practice to attempt to retain the ankle prosthesis when the infection is acute, particularly when it occurs during the early postoperative period. There are a number of treatment options available for infected TAA that includes surgical debridement, retention of the prosthesis and administration of intravenous antimicrobial therapy (DAIR), one or two-stage exchange arthroplasty, arthrodesis or amputation.

TAA infection literature cautions that great attention should be paid to delayed wound healing and its association with infection [5–10]. van der Heide et al. reported on the outcome of 58 TAAs in 51 patients with underlying rheumatoid arthritis (RA) or juvenile inflammatory arthritis (JIA) who had Buechel-Pappas or STAR implants [5]. Among this cohort, three patients (5%) developed early surgical site infection (SSI) and one of three (33%) patients treated with the van der Heide SSI protocol went on to develop a deep infection. The SSI protocol involved exploration of the surgical site, debridement of the wound and administration of systemic and local antibiotics. The ankle that developed deep infection underwent resection of the implant and subsequent fusion at six months. Further, Patton et al. reported on 29 cases of infected TAA and noted that 9 of the 29 (31%) infected TAAs were cases of delayed surgical wound healing that went on to deep infection [6].

Irrigation and debridement (I&D) can be a key first-step treatment of early TAA infections (early being defined as less than four weeks from the index TAA or remote hematogenous infection with symptoms less than four weeks) [7,11,12]. In a level III prognostic study, Kessler et al. defined infection parameters and proposed a treatment algorithm [7]. They selected 26 patients with PJI of TAA and matched patients with two control groups with 52 patients in each group. From this prognostic study, Kessler et al. proposed a diagnostic criteria for TAA infection which was based on presence of clinical

signs of pain, effusion, erythema and induration as well as one of the following criteria: (1) same microorganism growth in two or more cultures of synovial fluid and/or periprosthetic tissue, (2) visible pus surrounding the joint, (3) acute inflammation upon histopathological examination (greater than or equal to 10 neutrophils/high-power field) or (4) the potential to probe the base of a wound at the implant. They defined exogenous cases as locally acquired through the wound and hematogenous cases had an uneventful postoperative course for a minimum of *three months* after the initial TAA and/or there was a distant infection source. Four of 26 (15%) TAA infections were hematogenous in origin, and 22 of 26 (85%) TAA infections were exogenous. Meanwhile, *Staphylococcus aureus* and then coagulase-negative staphylococci were the most common pathogens. When compared to the control, risk factors for developing deep infection included persistent wound dehiscence (odds ratio (OR) = 15.38, 95% confidence interval (CI) = 2.91 to 81.34, p = 0.01, in comparison with both control groups) and secondary wound drainage (OR = 7.00, 95% CI = 1.45 to 33.70 in comparison with the age/sex-matched group and OR = 5.31, 95% CI = 1.01 to 26.78 in comparison with the time-matched group, p £ 0.04).

The TAA literature reports upon the success of irrigation and debridement (I&D) in early postoperative cases. Mann et al. reported on 84 ankles in 80 patients with a mean follow-up of 9.1 years with a 3 in 84 (3.5%) incidence of deep infection [10]. All deep infections were exogenous and occurred immediately postoperatively as a result of incomplete wound healing. Mann et al. treated all deep infections with open debridement and six weeks of intravenous antibiotics. One of the deep infections required a local skin graft and another required a free vascularized tissue flap for closure. No metallic prostheses were removed and there was no evidence of recurrent infection with an average follow-up of 9.3 years [10]. These results demonstrate the success of early debridement. Further demonstrating the success of I&D amongst exogenous cases, Nodzo et al. reported on 75 ankles with Salto Talaris prostheses. One of the 75 (1.3%) went on to develop deep infection within the first three weeks following TAA [11]. The patient was treated with I&D and intravenous antibiotics and the patient retained all components. Similarly, Borenstein et al. reported one ankle out of 65 consecutive TAAs (1.5%) that experienced deep infection [12]. The patient was treated with I&D and six weeks of intravenous antibiotics. Additionally, Patton et al. demonstrated the merits of I&D in detailing 29 cases of infected TAA [6]. If an I&D and revision arthroplasty were performed, 23 of 29 (79%) limbs were salvaged. Meanwhile, if revision TAA alone was performed, 19 of 29 (65%) TAA retention was reported.

In addition to I&D, the literature details the effectiveness of polyethylene liner exchange in cases of early postoperative infection and remote hematogenous infection when symptoms extend for less than four weeks [14–17]. Claridge et al. responded to the 2 of 28 (7%) cases of deep infection with polyethylene exchange only [13]. Similarly, Stoodley et al. detailed polyethylene liner exchange as an important early treatment step [16].

Reports on revision TAA after deep infection are variable [15,16,18–21]. In a case report describing TAA infection after a routine dental procedure, Young et al. described the work-up, blood cultures positive for *Streptococcus mitis* and a 6-week course of antibiotics with penicillin G and 18 million units intravenously daily for one additional week [17]. The patient remained non-weightbearing in a CAM boot until revision TAA surgery at three-months post-infection. Good outcomes with the patient walking pain-free at 16-month follow-ups were recorded. While Sproule et al. also opted for a revision TAA to treat the 1 of 88 (1%) for deep infection, they opted for a two-stage revision and recounted successful results [18]. Further reports of metal component revision after deep infection TAA demonstrated good results [15,19].

In a retrospective case series on 613 TAA, the 19 cases of deep infection were treated by established algorithms depending on if they were exogenous or late chronic infection [14]. For exogenous infection, Myerson et al. attempted prosthesis retention for 4 of 19 (21%) implants. Three (16%) had early post-op infections at three, five and seven weeks following initial implantation. All had I&D plus polyethylene liner exchange and later antibiotic therapy. One (5%) had an acute hematogenous infection. In this strategy, all four patients had recurrent infection and went on to require removal of the implant and staged treatment. Meanwhile, 15 of 19 (79%) deep infections in this series were late chronic infections. Of the deep infections, seven revision TAA were attempted but only three (16%) were successful. Of the four that failed revision TAA, three had recurrent infection and one aseptic loosening. Otherwise, for successful revision surgery, six patients were converted to arthrodesis; seven patients had a permanent antibiotic spacer, and three patients underwent transtibial amputation. The mean time to revision TAA or arthrodesis following initial infection treatment was 7.8 months (range, 2.5 to 13 months).

Revision TAA after late chronic infection has no consensus, and others advocate for conversion to arthrodesis in the case of infected TAA [8,15,22–25]. As reported by Myerson et al., six patients converted to arthrodesis all had successful revision, but only three of seven (43%) TAA revisions were successful [14]. Additionally, McCoy et al. reported on three failed TAAs due to infection [22]. These patients were revised using circular external fixator-assisted ankle arthrodesis and distraction osteogenesis for limb length equalization. All patients reported solid pain-free fusion and good subtalar joint alignment. Further evidence of good results, Mulhern et al. recounted the successful conversion to tibiotalocalcaneal arthrodesis with custom titanium alloy truss and retrograde intramedullary nail after revision TAA polyethylene became infected with *Staphylococcus aureus* [23]. Devries et al. added evidence to support arthrodesis instead of revision TAA after infection [24]. In their case series of five revision TAAs, Devries et al. initially converted the one deep infection directly to a revision TAA. While the deep infection was cleared at the time of replacement, the revision TAA went on to develop an infection. After failing two courses of long-term IV antibiotics, an antibiotic spacer was implanted and later converted to a tibiotalocalcaneal arthrodesis.

However, if deciding to proceed with a revision TAA after deep infection, there is evidence to support that single hydroxyapatite component coating should not be used in the revision [25]. When examining 117 consecutive ankles in which TAA failed after mean 4.3 years, Hinterman et al. found that 9 of 117 (8%) TAAs failed due to infection [26]. Avoiding single hydroxyapatite component coating, the group reported that the custom long-stemmed talar implant had good results amongst revisions with a 100 in 117 (85%) success rate, and one revision TAA attributed to deep infection.

While wound closure for deep infection is a coordinated effort with plastic surgery, plastics' perspective on wound closure for infected TAA is valuable when discussing a TAA infection algorithm. Goldstein et al. reported on two infected TAA treated for random local flap for wound coverage of the ankle [9]. Patients presented at a wound healing center for random local flap for wound coverage of the ankle. "Patient 3" required two flaps for infected TAA with lateral ankle wound: one peroneus longus muscle flap with hardware as exposed structure and one fasciocutaneous transposition flap with fibula as the exposed structure. "Patient 3" required 4 total operations and had a 55-day follow-up with no resultant complications. Meanwhile, "Patient 9" required two flaps for infected TAA with lateral ankle wound: one lateral calcaneal artery fasciocutaneous flap with hardware as the exposed structure and one fasciocutaneous transposition flap with hardware as the exposed structure. "Patient

9" required 2 total operations and had a 75-day follow-up with no resultant complications.

QUESTION 2: What is the optimal (type, dose and route of administration) antibiotic treatment for patients with infected total ankle arthroplasty (TAA)?

RECOMMENDATION: Though literature specific to TAA is lacking, based on recommendations for the management of hip and knee arthroplasties, the choice of antibiotic should be made based on the identification and sensitivities of the infecting organism(s). Dosing, frequency and route of administration of antibiotics may be determined in consultation with an infectious disease specialist and by taking into account the patient's weight and comorbidities, such as renal impairment and the antibiogram.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

There is a paucity of literature regarding the treatment and outcomes of periprosthetic joint infection (PJI) in TAA. The two largest studies on post-TAA infection from the United States report the use of six weeks of intravenous (IV) antibiotic therapy following surgical treatment of the infection [1,2]. In a study from Europe, Kessler et al. reported the use of one to two weeks of IV antibiotics followed by three months of oral antibiotics following surgical treatment for infection [3]. In all of these studies, the choice of antibiotic(s) was made based on the identified infecting organism(s) and its antibiotic sensitivity and with the assistance of an infectious disease specialist. In general, the most common pathogens responsible for PJI are *Staphylococcus aureus* (methicillin-susceptible or -resistant), coagulase-negative Staphylococci and other constituents of the skin's bacterial flora [4,5].

The timing of PJI following TAA is also important in determining infection management. If the infection developed within 6-12 weeks of implantation, this is considered an acute infection and debridement with retention of the implants (DAIR) and antimicrobial treatment are the most desirable approach. Conversely, for a device that has been present for more than three months, a chronic infection is presumed to be present, and a one- or two-stage exchange with antimicrobial treatment is the desired course of action [5–7].

In the hip and knee literature, there has been a debate with regards to the duration of antibiotic treatment. Some studies have recommended as many as three to six months of antimicrobial therapy following surgical intervention, depending on the organism [6,8]. However, other studies have shown six weeks of IV antibiotics to be a sufficient duration of treatment [9–11].

The theoretical benefit of a shorter course of antibiotics, aside from patient convenience, includes a reduced risk of adverse drug events (ADEs), including anaphylaxis, nephrotoxicity, hepatotoxicity and infectious colitis, as well as bacterial resistance [12]. The International Consensus on Periprosthetic Joint Infection stated that the duration of antibiotic therapy following removal of implants is inconclusive but recommended a period of antibiotic therapy between two to six weeks [13].

The authors of the Infectious Diseases Society of America (IDSA) Guidelines for the Diagnosis and Management of Prosthetic Joint Infection make the following recommendations for the management of hip and knee arthroplasties while suggesting that similar recommendations can be extended for the management of TAA infections [6]. The IDSA recommends four to six weeks of pathogen-specific IV or highly bioavailable oral antibiotic therapy following removal of implants, regardless of organism or in non-staphylococcal PJI treated with DAIR. They recommend two to six weeks of IV antibiotics in combination with oral rifampin, followed by 3 months of rifampin plus a companion oral antibiotic for a staphylococcal TAA PJI treated with DAIR. If rifampin cannot be used because of an allergy or toxicity concern, the IDSA recommends four to six weeks of IV antibiotic therapy. Of note, the IDSA recommendations are the same in the setting of a one-stage exchange as they are following DAIR [6].

Further studies on the treatment and outcomes of infection in TAA are needed. For now, we must rely on the hip and knee arthroplasty literature as well as the recommendations of the MSIS and IDSA.

QUESTION 3: Is there a role for suppressive antibiotics in patients with perioperative joint infection (PJI) of total ankle arthroplasty (TAA) who have undergone surgical treatment?

RECOMMENDATION: Culture-directed antibiotic therapy is recommended for patients undergoing surgical treatment of infected TAA. Routine administration of suppressive antibiotics in patients with an ankle prosthesis in place is not warranted; however, in certain clinical circumstances, this may be of benefit.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

There is scant literature related to the management of infected TAA. The available reports have been reviewed to determine if there is a role for routine administration of suppressive antibiotics after surgical management of infected TAA. The published studies do not address the issues of suppressive antibiotic therapy after infected TAA.

Myerson et al. reported on 19 patients with infected TAA [1]. In early acute infections, patients were treated surgically with irrigation and debridement (I&D) and polyethylene exchange, followed by six weeks of antibiotics. Of the four patients treated with this approach, all had persistent infections and required prosthesis removal. No comment was made regarding suppressive antibiotics after staged revision for infection. Patton et al. reported on a series of 29 TAA infections [2]. Acute infections were treated with polyethylene exchange and I&D. Of 14 acute infections, only three were treated successfully with this approach. Again, no comment was made regarding suppressive antibiotics after staged revision.

There is also little related to this question in the hip and knee literature. A recent study supported by The Knee Society evaluating this issue after surgical management of infected TAA found that

administration of suppressive antibiotics after reimplantation of the knee in patients undergoing two-stage exchange arthroplasty resulted in lowering the rate of subsequent failure [3]. The authors of the study stated that the findings were preliminary and further long-term data on the cohort was needed.

There are many potential issues related to administration of routine suppressive antibiotic therapy after surgical management of infected prosthetic joints. Cost, the potential for emergence of antimicrobial resistance, systemic adverse effects and so on are some of these potential issues. Therefore, and in the absence of concrete data, we believe that routine administration of suppressive antibiotic therapy for patients with a prosthetic ankle joint in place is not warranted. We realize that patients with infected TAA need to be treated on an individual basis and administration of oral antibiotics to some patients, such as those with extensive comorbidities, those infected with resistant organisms and those with complex infections may be justified in some circumstances.

QUESTION 4: What determines the type and dose of antibiotic that is needed to be added to the cement spacer in patients with infected total ankle arthroplasty (TAA)?

RECOMMENDATION: We recommend tailoring the antibiotic in cement spacers to the infecting organism if it has been identified, as is typically done in total knee and hip arthroplasty. Otherwise, broad-spectrum antibiotics may be utilized. Medical comorbidities should always be considered, especially with regard to renal function and allergy profile. A thermostable antibiotic should be added to cement.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

TAA is performed much less frequently than total hip and knee arthroplasty, and reports related to deep infections and associated management are limited.

Like hip and knee arthroplasty, management of infected TAA may include removal of prosthesis and insertion of an antibiotic-impregnated cement spacer. An antibiotic spacer, as part of two-stage exchange arthroplasty, has been utilized in the management of infected TAA. Lee et al. described the use of cement mixed with 1 gm gentamicin, 1 gm vancomycin and 1 gm cefazolin in nine patients with infected ankle joints, three of whom were status post TAA [1]. The infecting organisms of the three TAA patients included methicillin-resistant *S. aureus* (MRSA), methicillin-resistant *S. epidermidis* (MRSE) and *Enterococcus*. The authors utilized their technique with the intent of permanent spacer use and a return to weightbearing, as multiple lower extremity operations have been associated with amputation.

Given the fragile soft tissue envelope around the ankle, Ferrao et al. also describe the use of a definitive antibiotic spacer after ankle infection [2]. Six of nine patients were status post-TAA and required explantation due to infection. The authors indicated that culture-specific antibiotics were mixed into cement when possible, although the detailed combination was not listed. If the infecting organisms were not isolated by culture, 2 gm vancomycin and 1.9 gm gentamicin were mixed into the cement. Bacteria were isolated in seven of the nine patients: *Staphylococcus aureus* (n = 3), *Staphylococcus epidermidis* (n = 3) and *Streptococcus viridans* (n = 1). Three patients required additional surgery, including two patients who underwent below-the-knee amputations.

In a large series including 966 patients, 29 patients were identified with infection after primary or revision TAA [3]. Cement spacers were placed in 17 cases, although the antibiotic formulation of the spacers was not indicated. The most common infecting organisms included methicillin-sensitive *S. aureus* (MSSA), coagulase-negative staphylococci and polymicrobial infection (one of which included MRSA).

Fifteen deep infections were identified in another series including 613 primary and revision TAAs at a single institution [4]. An additional four deep TAA infections from outside facilities were also treated during the study period. Antibiotic spacers formulated with 1 gm vancomycin and 1.2 gm tobramycin per cement packet were used for chronic infections requiring explantation. The infecting organisms included coagulase-negative Staphylococcus (n = 6), MSSA (n = 4), MRSA (n = 2), *C. acnes* + coagulase-negative Staphylococcus (n = 1), *E. coli* (n = 1), *S. viridans* (n = 1) and polymicrobial including MRSA (n = 1). Four attempted reimplantations were performed, but all subsequently failed due to infection with coagulase-negative Staphylococcus and MSSA.

Another study documented 26 TAA infections in a cohort of 408 patients at a single institution [5]. The most common infecting organisms included *S. aureus* (n = 8), coagulase-negative Staphylococcus (n = 8), *Enterococcus* (n = 4), polymicrobial (n = 4), *Enterobacter* (n = 3), *Klebsiella* (n = 2), *C. acnes* (n = 2) and MRSA (n = 1).

If the infecting organism is known prior to explantation based on preoperative aspiration, the use of tailored antibiotics incorporated into the cement spacer is recommended [3]. This has been recommended in total hip and knee replacement and can be extrapolated for use in the ankle [6,7]. Antibiotic-laden spacers result in higher antibiotic concentration at the infected site for a longer duration than that achieved with systemic antibiotics alone [8]. Tailoring the antibiotic selection is important to avoid breeding unneces-

sary resistance that has been identified after aminoglycoside-impregnated spacers [9].

Antibiotic selection requires consideration of a number of factors. Cultures from preoperative aspiration are informative; however, draining sinus cultures may have contaminating organisms [8,10,11]. Consultation with a microbiologist or infectious disease service may be helpful to determine an appropriate preparation for the cement spacer [12]. If no organism is identified, antibiotics with broad-spectrum coverage may be utilized [6,8,13,14]. One study showed effective eradication of infection with the use of 2 gm vancomycin, 2 gm gentamicin and 2 gm cefotaxime per 40 gm packet of cement for broad-spectrum coverage [7]. This combination is effective against MRSA (vancomycin), gram-negative bacteria including Pseudomonas (gentamicin) and gentamicin-resistant organisms (cefotaxime) [15].

When selecting an appropriate antibiotic profile for the cement spacer, factors to consider include thermostability, water solubility, patient allergy and availability as a sterile powder [7,16]. Some of the available options include gentamycin, vancomycin, ampicillin, clindamycin, tobramycin and meropenem [7,12,17]. Tobramycin is commonly used and has been shown to be stable during the exothermic reaction of cement mixing and elutes in high concentration to be effective against multiple common bacteria implicated in periprosthetic joint infection [18].

Combining antibiotics may result in higher local antibiotic concentration than individual antibiotics. Vancomycin combined with imipenem-cilastatin eluted higher concentrations of antibiotic and for a longer duration when compared to in vitro elution of vancomycin-impregnated cement alone [19]. Similar findings have been shown with vancomycin combined with tobramycin [20]. Tobramycin also has been shown to elute in higher concentration and for a longer duration than vancomycin [21]. Tobramycin, gentamicin and vancomycin are the most commonly used antibiotics, but others have been described and may be utilized depending on patient allergy profile, bacterial resistance and fungal infection [22].

The additive effect seen with certain antibiotics may be related to the higher solvent concentration in the cement that can diminish structural integrity but increase surface area for elution. To that effect, mixing the cement and antibiotic without vacuum assistance is theoretically superior since porosity is increased [23]. Palacos (Heraus; Wehrheim, Germany) cement seems to have a better profile for use than Simplex (Stryker; Mahwah, NJ) cement in multiple studies that show antibiotic elution in higher concentrations and for a longer duration [21,24–26]. In general, mixing more than 5 gm of additional powdered antibiotics into cement is not recommended because of its effect on the mechanical strength of the cement and potential for systemic toxicity [27]. Some antibiotics, such as rifampin, have been shown to interfere with cement curing and may not be ideal for use [28]. However, new technology with alternative delivery systems, like rifampin in microencapsulating in alginate beads, may allow broader coverage of infecting organisms as greater rates of antibiotic resistance emerge [28].

Common doses of antibiotics added to cement for treatment of periprosthetic joint infection are shown in Table 1. There are a wide variety of published quantities of antibiotics, with the trend generally going towards higher doses. However, a recent study demonstrated that higher dose antibiotics are not necessarily associated with the best elution properties; optimal in vitro antibiotic dosage in terms of elution rate and duration included tobramycin 3 gm and vancomycin 2 gm [29]. Vancomycin 2 gm per 40 gm packet of cement has been shown to meet the minimum inhibitory concentration (MIC) for five weeks after implantation [19,23]. Some antibiotics such as cefazolin, ciprofloxacin and ticarcillin, do not maintain adequate elution levels and are therefore less favorable for use [30].

TABLE 1. Antibiotic additives to cement for treatment of periprosthetic joint infections

Antibiotic	Activity Against	Quantity per 40g Cement Packet	Notes
Vancomycin-P	Gram-positive bacteria including methicillin-resistant organisms	2 gm [19,23]	
		4 gm	Studied in combination with ceftazidime 4 gm for broad-spectrum coverage [45]
Tobramycin	Gram-negative bacteria including *Pseudomonas*	2.4 gm [46]	
		4.8 gm [47]	
Daptomycin	Gram-negative bacteria	1 gm [25]	
Amikacin	Gram-negative bacteria and *staphylococcus*	1 gm [25]	
Clindamycin	Gram-positive cocci and anaerobes	6 gm [30]	
Imipenem/Cilastatin	Broad spectrum including gram-positive and gram-negative including *Pseudomonas* and *Enterococcus*	2 gm	Studied in combination with vancomycin 2 gm [19]
Ceftazidime	Gram-negative bacteria including *Pseudomonas*	4 gm	Studied in combination with vancomycin 4 gm for broad-spectrum coverage [45]
Amphotericin B	Fungal infections	100-150 mg [48]	

During the addition of antibiotics to cement, drug metabolism and concentration should also be considered. In addition, the medical comorbidities of the patient, such as renal function and allergy profile, should be considered, as these will influence the dose of antibiotics to be added to the cement and may preclude certain classes of antibiotics to be used. The incidence of acute kidney injury due to elution of antibiotics from a cement spacer has been reported to range between 4.8 and 20%, as aminoglycosides and vancomycin are both renally excreted [7,31–34]. Furthermore, a high concentration of certain antibiotics may be detrimental to local tissues and affect healing. Tobramycin can decrease cell growth if the concentration is greater than 400 micrograms/mL [35]. Gentamicin levels greater than 100 micrograms/mL have cytotoxic effects on osteoblasts, and this threshold is commonly exceeded for ten days after implantation of a spacer with gentamicin [36–38]. Vancomycin appears to be safe as long as the concentration is under 1,000 micrograms/mL [39].

Because of the risk of bacterial contamination may increase with time, the duration of an antibiotic spacer in situ should be limited. This is especially true if revision TAA is planned. The spacer may become colonized in 15 to 50% of cases, and the odds ratio of reinfection when positive culture is obtained from a cement spacer is eight times [40]. Recently, resistant bacteria have been identified on antibiotic-cement beads at the time of reoperation [41]. The antibiotic elution decreases over time, which reaffirms limiting the duration of spacer use [40,42–48].

Based on our understanding of the available literature, including much related to management of infected hip and knee arthroplasties, we recommend that 2 gm of vancomycin and 2.4 gm of tobramycin be mixed with every packet (40 gm) of methylmethacrylate cement to allow for coverage of a broad spectrum of organisms. In some infected TAA cases, additional or alternative antibiotics may be needed based on the identity of the infecting organism(s) and the antibiogram. Unless used as definitive treatment, the cement spacer should not be left in situ for too long because of the potential for the spacer to act as foreign material after antibiotic elution is completed (usually within a few weeks).

QUESTION 5: What are the indications and contraindications for irrigation and debridement and retention of prosthesis (DAIR) in patients with infected total ankle arthroplasty (TAA)?

RECOMMENDATION: DAIR with polyethylene exchange may be indicated in early postoperative infection (< four weeks) or acute hematogenous infection (< four weeks of symptoms) in patients with infected TAA, although recurrent infection has been seen. Sufficient clinical evidence is lacking.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Periprosthetic joint infection (PJI) is a serious complication after TAA. Deep infection of TAA can be limb-threatening; hence, prompt treatment is required to minimize the potentially devastating effects of infection. Currently reported infection rates after TAA range from 1.1 to 8.5%, with reports indicating that newer anatomic designs have lower overall infection rates [1–6].

The current indications for DAIR in infected TAA include early postoperative infection and acute hematogenous infection. Myerson et al. retrospectively reviewed 572 TAAs over a 10-year period and found 19 cases of PJI (3.3%), including 15 chronic infections, three early postoperative infections, and one acute hematogenous infection [7]. The three early postoperative infections and one acute hematogenous infection were treated with initial irrigation and debridement with polyethylene liner exchange. All four cases resulted in recurrent infections that were treated with successful revision TAA, tibiolacalcaneal fusion and antibiotic cement spacer with an average retention time of six months. Only one case had an initial negative culture. The authors postulated that the inability to eradicate bacteria could be secondary to the ankle's unique anatomy with difficult access to regions such as the posterior gutters to perform a complete debridement. Additionally, Patton et al. reviewed 966 TAA over a 17-year period and found 29 cases of infected TAA (3.2%) [8]. They treated acute infections with polyethylene exchange in two cases and debridement alone in three cases. All five cases were apparently treated successfully with no evidence of subsequent failure.

There is paucity in the current literature regarding the management of PJI of TAA. Indications for DAIR are limited to early postoperative infection and acute hematogenous infection, and most guidelines are derived from the knee and hip studies. There are mixed results even in this selected group of patients, as all four patients with early infection from one study suffered persistent infection following DAIR, raising questions regarding the efficacy of this procedure. It is unclear at this point whether the failures stem from inadequate debridement due to the unique anatomy of the ankle or whether the natural history of ankle infection is inherently different than that of the hip and knee. Larger and additional studies are needed to provide a higher level of recommendation at this point.

QUESTION 6: What is the optimal protocol for performing debridement, antibiotics and implant retention (DAIR) in an infected total ankle arthroplasty (TAA) (type and volume of irrigation solution, and so on)?

RECOMMENDATION: DAIR in acute TAA infections may be an acceptable treatment option. If performed, DAIR should be done meticulously, ensuring that all necrotic or infected tissues are removed and modular parts of the prosthesis, if any, exchanged. The infected joint should also be irrigated with antiseptic solutions.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

For total hip and knee periprosthetic joint infection (PJI), the DAIR procedure is a viable alternative to explantation or one-stage revision in cases of early infections by a relatively antibiotic-susceptible bacteria, in the absence of mechanical problems or a sinus tract. Concerning TAA infections, these general prerequisites for DAIR are not different than for other PJIs, but the success of DAIR in TAA infection is relatively poor (see Table 1). The best evidence is reported by Kessler et al. [1]. The authors investigated 34 cases of TAA infection, of which 21 were treated by DAIR. Remission using the DAIR procedure was achieved only in two-thirds of all cases (14 of 21, 67%) [1].

The reason for failure of DAIR in hip and knee PJI cases has been linked to resistance of bacteria, poor host and inability to remove modular components, which would then compromise the ability to perform meticulous debridement. Most surgeons will agree that the aforementioned factors are important ones influencing the outcome of DAIR. They will also posit that one of the most important metrics governing the success of DAIR is the method used by the surgeon to perform the procedure. Meticulous debridement and the use of copious antiseptic solutions are all believed to be an important part of bioburden reduction, which in turn affects the outcome of this procedure [4–6]. When DAIR is attempted, available literature infrequently gives in-depth insight into the surgical details – approach, volume and type of irrigation solution or, perhaps most importantly, the frequency of poly exchange versus retention.

Practically, the anterior approach is most commonly described [1–3] and poly-exchange frequently endorsed [3,4]. The duration of concomitant antibiotic prescription is most commonly six weeks of therapy (most commonly intravenous); however not all routes of administration or duration is conveyed in the literature reviewed [1–4,6]. The use of vacuum-assisted devices is not reported in the treatment of TAA infections, rather in the promotion of wound healing and the prevention of infection after primary elective arthroplasty [7,8].

TAA, total ankle arthroplasty; DAIR, debridement, antibiotics and implant retention

Authors: Kent Ellington, Thomas B. Bemenderfer

QUESTION 7: What are the indications for one-stage versus two-stage exchange arthroplasty in management of the infected total ankle arthroplasty (TAA)?

RECOMMENDATION: Two-stage exchange arthroplasty is recommended in the majority of cases following infected TAA. One-stage arthroplasty is only indicated in a limited patient population with acute infection, preoperatively identified low-virulence organisms and low-risk patient factors.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 92%, Disagree: 8%, Abstain: 0% (Super Majority, Strong Consensus)

RATIONALE

The management of the infected arthroplasty remains a challenging and controversial topic in relation to any joint [1–5]. Reported rates of infection following TAA requiring re-operation (surgical irrigation and debridement (I&D), component removal and exchange, or revision) range from 0 to 8.6% [6–11]. Special consideration must be taken into account in the management of the infected total ankle given the tenuous soft tissue coverage, frequent history of multiple preceding operations, and, relative to hip and knee arthroplasty, a more recent arthroplasty design and more limited experience [12]. Currently, two-stage revision exchange arthroplasty surgery is the most popular surgical option for the management of periprosthetic joint infection (PJI) in North America and worldwide. However, it may result in significant bone loss, patient morbidity and prolonged disability, leading to a more challenging reconstruction and ultimately prolonged recovery, poorer patient-reported clinical functional outcomes, higher rates and risk of subsequent infection and potential failure of salvage operations leading to amputation.

Surgical treatment goals of the infected TAA are to eradicate the infection, obtain mechanical stability and soft-tissue coverage, alleviate pain and maximize clinical function. Historic treatment strategies have included antibiotics with hardware retention, aggressive debridement with or without polyethylene exchange and removal of hardware and exchange or arthrodesis in one or two stages with an antibiotic-impregnated cement spacer.

Extreme care should be taken when considering appropriate management of the infected TAA. Kessler et al. published the largest study to date evaluating 34 patients following revision TAA for infection [10]. An infection-free outcome with satisfactory function of the ankle was obtained in only 23 patients (67.6%). One-stage revisions with retention of one or both components resulted in 33.3% (7/21) failure with persistent infection, whereas two-stage revision with explantation of all components results in 10% (1/10) failure. Myerson et al. retrospectively evaluated 19 revision cases, and only 3 of the 19 patients underwent successful revision with replacement (15.7%), 6 with arthrodesis (31.6%), 7 with a permanent antibiotic spacer (36.8%) and 3 patients required a transtibial amputation (15.7%) [11]. Although prosthesis salvage was attempted in three early postoperative and one acute hematogenous cases, all revision cases ultimately required subsequent removal of the prosthesis. Whereas Myerson et al. reported that no patient was successfully treated with retention of the hardware, Patton reported conflicting results with four of four patients (100%) successfully treated with retention of hardware and irrigation and debridement (two with and two without exchange of polyethylene liner) for heterogeneous presentations (one acute presentations with cellulitis, one acute presentation with dehiscence, one late chronic, and one remote hematogenous) [12]. However, the majority of the patients in this study were treated with two-stage revision arthroplasty or amputation with retention of arthroplasty only achieved in 19 (65%) cases of infection (n = 29). Given the currently available literature, there are conflicting data for the utility of surgical I&D with retention of hardware. Future studies are necessary to evaluate the feasibility of surgical I&D of PJI in TAA.

To date, there is no level I evidence that provides indications or contraindications for a one-stage exchange arthroplasty in TAA. Furthermore, there are no randomized controlled trials that provide absolute indications or contraindications for two-stage exchange arthroplasty in hip and knee arthroplasty [13–16]. Care must be taken to determine the need for implant removal given that the reported success of treating the infected TAA with retention of one or both implants ranges from 0 to 100% [7,11,12]. Given the variability in the reported rates of success in eradicating infection, morbidity and mortality among observed patient populations and variable time periods prior to reimplantation, direct comparisons with one-stage exchange arthroplasty are difficult due to a patient selection bias in the current literature [15–18]. Although no literature is available with respect to TAA, a recent systematic review of the knee arthroplasty literature by Romano et al. demonstrated that a two-stage exchange provides, on average, a better outcome with respect to the control of infection in the knee [19]. The same group recently presented similar but less notable findings for the hip [20]. It is not clear how these findings would translate to the ankle, and future studies are necessary to better understand the potential for infection control and functional outcome with one- versus two-stage revision arthroplasty.

There are, however, circumstances that necessitate the removal of implants. Systemic infection necessitates timely administration of appropriate antibiotics and prompts removal of implants with thorough debridement of the soft tissues and bone in order to address the potential life-threatening sequelae of PJI. The immunocompromised patient or the presence of medical comorbidities, including metastatic disease, advanced cardiac disease and renal and/or liver dysfunction, have been shown to impact the rate of success for infection eradication and certainly influence morbidity and mortality [7,10]. It is unknown if the presence of these comorbidities constitutes a contraindication for one-stage exchange arthroplasty in TAA [14–16,18,21,22].

Since 1999, when Costerton first attributed the persistence of certain chronic infections to the presence of biofilm, the majority of implant-related infections in orthopaedics are believed to be secondary to biofilm-related infections [23]. These infections are associated with glycocalyx polysaccharide biofilms that pose unique challenges including frequently being recalcitrant to antibiotic treatment and may be culture-negative with ineffective clearance from the host [24,25]. Failure to identify the offending organism and/or culture-negative PJI is a relative contraindication to one-stage exchange arthroplasty [13,16,26,27]. Given the risk of biofilm-related

TABLE 1. Indications for one- versus two-stage exchange for infected TAA

Treatment Type	Indications
One-stage Exchange Arthroplasty	No sinus tract or exposed hardware Healthy patient and soft tissue No prolonged antibiotic use No significant bone loss requiring bone graft Low-virulence Organism with good antibiotic sensitivity
Two-stage Exchange Arthroplasty	**Sepsis.** Patients with systemic manifestations of infection **No Cultured Organism.** High suspicion for infection but no organism has been identified **Antibiotic-resistant Organism.** Preoperative cultures identifying difficult to treat and antibiotic-resistant organisms **High-risk Patient Factors.** a. Presence of a sinus tract or exposed hardware b. Immunocompromised c. Inadequate and non-viable soft tissue coverage d. Need to utilize higher order reconstructive techniques (bone graft, augmentation, soft-tissue flaps)

TAA, total ankle arthroplasty

infections, several authors advocate that reimplantation of a prosthesis should be delayed until adequate resuscitation and eradication of the offending organism have been confirmed [13–16,21,26–31].

The presence of compromised soft tissues (e.g., sinus tract, exposed hardware, etc.) that may limit adequate implant coverage is another indication for two-stage exchange arthroplasty. Sinus tracts frequently present with indurated, poorly elastic surrounding tissue near and around the ankle that limits the potential for adequate primary closure. In addition, the presence of a sinus tract may contaminate preoperative cultures and preclude the prerequisite for the identification of the offending organism [4,13,16,26,27]. Tissue expanders, musculocutaneous flaps and possible repeat debridements may all be indicated, necessitating further time between initial resection and reimplantation [14–16,22]. If soft tissue coverage cannot be obtained at index revision of a one-stage exchange arthroplasty, a two-stage surgery should be considered [13–15].

If the decision is made to pursue two-stage arthroplasty, there is no definitive evidence in the literature concerning the optimal timing between the two stages. However, there should be ample time to allow administration of a complete full course of antibiotics, eradication of the offending organism supported by a decrease in inflammatory markers (C-reactive protein [CRP]/erythrocyte sedimentation rate [ESR]), and adequate soft tissue preparation. Although no literature exists demonstrating the optimal timing of replantation in TAA, there is evidence that replantation prior to completing a complete six-week course of antibiotics may result in increased positive cultures at the time of surgery in the hip and knee [14,16]. In the United States, the most common practice is to complete a course of six weeks of intravenous or oral antibiotics followed by a cessation of antibiotics for two to eight weeks prior to reimplantation [16,32,33]. In addition, in the adult hip arthroplasty literature, there is evidence that delaying replantation beyond six months impairs functional improvement compared to patients who underwent two-stage exchange within six months of resection and reimplantation [34]. Although we recommend trending the ESR and CRP, the need for serologic evaluation prior to reimplantation is unclear. Although ESR and CRP alone are poorly diagnostic of persistent PJI with no optimal cutoff values, changes in inflammatory marker values from the time of resection may demonstrate improved pathogen control and decreased overall biologic burden [15,35–37]. There is currently no literature with respect to TAA to guide decision-making on the optimal timing between exchanges, nor serologic cutoff values.

All patients, regardless of nonoperative or operative management, should be critically evaluated clinically and every effort to minimize the risk of wound breakdown should be pursued, including optimization of diabetes, reduction of inflammatory conditions, the absence of tobacco use and optimal nutrition. Soft tissue defects may require flap coverage. We recommend revision to ankle arthroplasty after clearance of infection.

QUESTION 8: What metrics can be used to determine the optimal timing of reimplantation in patients who have undergone resection arthroplasty as part of a two-stage exchange for infected total ankle arthroplasty (TAA)?

RECOMMENDATION: There is no conclusive data regarding what metrics can be used in order to determine the optimal timing of reimplantation for an infected TAA. We recommend that reimplantation is performed when there are clinical signs of resolution of infection (well-healed wound, lack of erythema, etc.), and the serological markers have substantially declined (> 40%) from baseline (measured at the time of diagnosis of infection).

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Infected TAA is a serious complication that is thought to occur in as many as 5% of patients [1,2]. Management of infected TAA often requires surgical intervention that includes removal of the prosthesis, local and systemic antibiotic treatment, and subsequent reimplantation in a select group of patients. One of the most challenging questions pertains to optimal timing of reimplantation. There is little in the literature regarding the optimal treatment of an infected TAA. Most of the available literature has limitations including low numbers of patients, short duration of follow-up and so on [1–5].

There are a number of publications related to patients with infected TAA who underwent two-stage exchange arthroplasty. Patton et al. reported on 29 of 966 (3.2%) cases of infected TAA [3]. Among the infected TAA, 13 patients underwent two-stage exchange arthroplasty and antibiotic spacer placement. While infection type and operative cultures were listed, no specific recommendations on timing of reimplantation were made. Similarly, Lee et al. omitted data regarding timing of reimplantation but reported one case of deep infection, out of 50 TAAs (2%) that required implant removal, antibiotic-impregnated spacer placement, and later revision TAA [4].

Thoroughly outlining the timeline, Young et al. detailed a case report of a two-stage TAA revision [5]. Irrigation and debridement (cefazolin 1 gm diluted in 1L 0.9% saline) and antibiotic cement

spacer (80 gm of polymethylmethacrylate impregnated with 2 gm gentamicin) placement was implemented. The blood cultures and intraoperative bone and tissue cultures in the latter infected case isolated *Streptococcus mitis*. As a result, a six-week course of antibiotics with penicillin G was administered. Three months after infection had resolved, the patient had a revision TAA. As demonstrated, the limited TAA infection literature warrants that a treating orthopaedic surgeon applies the basic treatment principles derived from infections of knee and hip arthroplasties [6].

The ultimate decision regarding surgical management of patients with infected TAA in general, and reimplantation of those who have undergone a prior resection in particular, lies with the orthopaedic surgeon with appropriate consultation of other disciplines such as infectious disease specialists, plastic surgeons and so on. A two-stage exchange strategy is commonly indicated in patients who have a chronic infection and are not candidates for a one-stage exchange arthroplasty. Protocols for management of a patient with infected TAA are extrapolated from the available literature for infected hip and knee arthroplasties. Patients undergoing resection arthroplasty typically receive four to six weeks of intravenous or highly bioavailable oral antimicrobial therapy between stages [7,8].

The timing to reimplant usually relies on signs of clinical resolution of infection, such as healing of the wound, absence of erythema and so on, as well as a decline in serological markers of inflammation, namely erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) [9]. To determine infection resolution and predict the presence of infection in patients awaiting reimplantation, numerous serological markers have been evaluated in the past, including interleukin 6 (IL-6) and others [10]. The most widely used serological tests for the diagnosis of periprosthetic joint infection (PJI) are the assessment of ESR and CRP level. A recent publication also suggested the use of serum D-dimer combined with ESR and CRP in order to increase sensitivity and specificity [11].

In data published about hip and knee surgery, time from resection arthroplasty to reimplantation varies significantly from two weeks to several months. In earlier cohort studies, early reimplantation within three weeks after resection resulted in a higher failure rate [12,13]. Some groups have reported satisfactory outcomes when reimplantation occurs two to six weeks after resection while systemic antimicrobials are still being administered in situations when the infection is not due to MRSA, enterococci or any multidrug-resistant gram-negative organisms [14]. Delayed reimplantation after four to six weeks of intravenous antimicrobial therapy and an antibiotic-free period of two to eight weeks has been highly successful and chosen as the "standard" currently [7,15–17]. Recently, synovial fluid biomarkers have been shown to be useful in reaching or refuting the diagnosis of PJI. The combined measurement of synovial fluid alpha-defensin and CRP for the diagnosis of PJI demonstrated a sensitivity of 97% and a specificity of 100% [11,18]. Not only is obtaining synovial fluid invasive and painful to patients, but also there are not infrequent occasions when either an inadequate amount of fluid is available to perform all tests, or, worse, no fluid is retrieved from the joint [11].

Obtaining a pre-revision ESR and CRP is recommended to assess the success of treatment prior to reimplantation [19]. However, as some groups have reported, an elevated CRP level and ESR may not be accurate in predicting persistent infection post-resection, therefore the need for subsequent debridement should be interpreted in the context of the entire clinical picture when deciding on the appropriate timing for reimplantation [20–22].

In the absence of concrete data, and borrowing from the hip and knee infection literature, we recommend that reimplantation in patients with infected TAA be performed when appropriate antibiotic treatment is completed, clinical signs for resolution of infection are present (healed wound, absent erythema and so on) and the level of inflammatory markers of acute inflammation (ESR, CRP and possibly D-dimer) have declined substantially (> 40%) from their baseline. Further research regarding this issue is desperately is needed.

QUESTION 9: What are the predictors of treatment failure in patients who have undergone two-stage exchange for infected total ankle arthroplasty (TAA)?

RECOMMENDATION: Predictors for treatment failure in patients undergoing two-stage exchange for infected TAA include compromised soft tissues (e.g., sinus tract, exposed hardware, etc.), significant bone involvement/osteomyelitis and insufficient timing of antibiotic course before reimplantation.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

The optimal management of patients with infected TAA is not well-known due to a limited number of studies [1–5]. While comparisons and deductions can be made from the knee and hip periprosthetic joint infection (PJI) literature on two-stage exchange, the management of infected TAA can differ from hip and knee arthroplasty because of the precarious soft tissue coverage around the ankle, the common history of multiple preceding operations in patients, and arthroplasty design updates coupled with limited surgical experience [3]. Two-stage exchange is a well-accepted surgical management approach for PJI.

There is limited detail in the TAA literature on two-stage exchange failure. A study by Patton et al. reported on 12 cases of two-stage revision for infected TAA but offered no details of the cases that failed [3]. Another study by Kessler et al. reported on 34 patients undergoing surgical management for infected TAA [6]. Of the patients treated for infected TAA, 10% (1/10) of two-stage exchanges resulted in failure. This two-stage failure is not described in detail. However, in the described cohort, the presence of compromised soft-tissue significantly increased the rate of failure after revision.

Another problem with the soft tissues surrounding the ankle is the presence of a sinus tract. Not only do sinus tracts often have indurated soft tissue around the ankle, but they also have the potential to limit preoperative cultures and organism identification, which in itself may predispose the patient to a future failure [7–11]. Furthermore, certain comorbidities such as metastatic disease, renal and/or liver dysfunction, and advanced cardiac disease are indicated to influence the rate of PJI [6,7], but these comorbidities may not necessarily be tied to treatment failure after two-stage exchange arthroplasty.

In North America patients undergoing two-stage exchange arthroplasty for the treatment of PJI are often subjected to six weeks of an antibiotic course. Based on data from hip and knee PJI, inadequate administration of antibiotics has been linked to the presence of positive cultures during reimplantation that, in turn, increase the risk of failure after reimplantation [8,13]. While inadequate antibiotic therapy has been linked with subsequent failure, the exact duration of antibiotic treatment, the benefit of intravenous (IV)-to-oral (PO) antibiotics, and the timing of IV-to-PO switch has not been determined. Recent PJI literature suggests that a short IV antibiotic period lasting at least five to seven days followed by pathogen-specific PO therapy may be a viable option for treatment of patients with PJI [14,15].

QUESTION 10: How should postoperative cellulitis be treated in patients with total ankle arthroplasty (TAA) in place?

RECOMMENDATION: In the absence of evidence, we recommend that (1) patients with TAA in place who develop postoperative cellulitis be evaluated thoroughly to rule out periprosthetic joint infection of the ankle, and (2) that isolated cellulitis may be treated with antibiotics, elevation and close monitoring. Aspiration can be considered in certain cases, with the potential risk of introducing deep space infection.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 92%, Disagree: 0%, Abstain: 8% (Super Majority, Strong Consensus)

RATIONALE

Treatment of postoperative cellulitis in patients with TAA is not well-defined. Schipper et al. suggested a compression wrap protocol over a circumferential fiberglass cast significantly reduces the incidence of wound complications [1]. While the authors demonstrated an overall reduction of wound complications, the differing postoperative immobilization protocols did not result in a significant difference in the proportion of wounds in patients with cellulitis requiring antibiotics (oral or intravenous) (22% vs. 16.7%, p = .60).

To our knowledge, there is no other TAA literature reporting on cellulitis. Brook and Frazier reported on 259 patients with culture-positive cellulitis [2]. Based upon their report in which 63 of 259 (24%) cellulitis cases were located on the leg, the authors concluded that the polymicrobial nature of cellulitis warrants the prescription of broad-spectrum antibiotics.

Meanwhile, in the total hip arthroplasty (THA) population, Rodriguez et al. reported on the use of intravenous and oral antibiotics in 16 patients with incisional cellulitis [3]. They assessed the erythematous eruption by hematological investigations, radiography, radionuclide scanning and blood culture, as well as aspiration from the area and skin biopsy. Following assessment, the best antibiotic course was determined. For two to six days until the erythema resolved, the following antibiotics were given to patients: 11 were given cephalexin, one vancomycin, one ampicillin and gentamicin and one cefuroxime. Following this antibiotic course, cephalexin, ciprofloxacin or amoxicillin were administered orally for two to six weeks. One patient received only oral ciprofloxacin, with resolution of the erythema occurring within 24 hours. Rodriquez et al. thus concluded that treatment with antibiotics for a minimum of two weeks led to resolution of symptoms and allowed for nonoperative management of the cellulitis.

In a separate case report on a patient undergoing THA, Perlick et al. argued that most cellulitis is caused by *Streptococcus hemolyticus* or *Staphylococcus aureus* [4]. The authors were successful in treating the surgical site cellulitis with the following protocol: dicloxacillin 2 gm × 3 or clindamycin 600 mg × 3 daily. This finding should also be considered when determining an appropriate treatment regimen for patients with post-arthroplasty cellulitis.

Authors: Jonathan Kaplan, Steven Raikin

QUESTION 11: Does deep chronic infection after total ankle arthroplasty (TAA) require implant removal?

RECOMMENDATION: Yes. Deep chronic infection after TAA requires implant removal unless otherwise contraindicated.

LEVEL OF EVIDENCE: Strong

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

While there is substantial evidence in the total hip arthroplasty (THA) and total knee arthroplasty (TKA) literature regarding one- and two-stage revision for infected total joint arthroplasty (TJA), there are very limited studies assessing deep chronic infection in primary TAA and TAA revisions. The majority of recommendations for the evaluation and treatment of the infected ankle arthroplasty in the current literature are based on those recommendations of THA or TKA [1–3]. Hsu et al. reported on the evaluation and management of the painful

TAA. In cases of deep infection in the early period (< 4 weeks), the authors recommended irrigation and drainage (I&D) with polyethylene exchange and intravenous (IV) antibiotics. In infection cases occurring > 4 weeks from the time of initial implantation, a two-stage surgery was required. However, it should be noted that this determination was again based on the THA and TKA literature rather than studies specifically assessing infected TAA [4].

Myerson et al. performed a retrospective review on the management of infection following total ankle replacement [5]. Over a 10-year period, the authors performed 613 total ankle replacements with a deep infection rate of 2.4%. There were 15 late/chronic infections, three early infections and one acute hematogenous infection. In the three early and one acute hematogenous infections, the authors attempted I&D, polyethylene exchange and retention of the components in conjunction with a course of IV antibiotics. Unfortunately, all four patients developed recurrent infection requiring repeat I&D and complete prosthesis removal with antibiotic spacer placement. In the chronic/late infections cohort, they performed a two-stage revision with initial I&D, complete explantation, cement spacer application and IV antibiotics. Of these 15 chronic infections, infection recurrence occurred in three patients, requiring additional interventions. Additionally, from the same institution, Ferrao et al. reported on the definitive treatment of infected total ankle replacements using an antibiotic cement spacer in cases in which revision would not be amenable [6].

In a related study, Patton et al. reported on their experience with infected TAA [3]. Out of 966 patients undergoing TAA, there were a total of 29 infections, accounting for an overall infection rate of 3.2%. They classified these based on acute postoperative complications including cellulitis or wound dehiscence, late chronic infection or remote hematogenous. There were 11 cases of acute postoperative wound dehiscence, three cases of acute postoperative cellulitis, eight cases of remote hematogenous infection and seven cases of late chronic infection. Of the 14 cases in the acute stage (cellulitis and wound dehiscence), one was treated with I&D, polyethylene exchange and antibiotic treatment, three were treated with I&D and antibiotics, four were treated with two-stage exchange revision, one was treated with a one-stage revision, one was treated with permanent antibiotic spacer placement and four were treated with amputation. Of the seven late chronic infections, five were treated with two-stage procedures, one was treated with amputation and one was treated with polyethylene exchange. In the eight cases of remote hematogenous infection, one was treated with amputation, six were treated with two-stage procedures and one was treated with I&D. While the authors report a variety of procedures for each of these presentations based on timing, it should be noted that they defined infection in the early postoperative phase as cellulitis and wound dehiscence rather than an objective diagnosis of deep infection. Additionally, while there were cases of single-stage procedures, these were quite low numbers compared to two-stage procedures or even amputation.

3.2. TREATMENT: NON-TOTAL ANKLE ARTHROPLASTY-SPECIFIC

Authors: Kent Ellington, Christopher Hirose, Thomas B. Bemenderfer

QUESTION 1: What is the treatment "algorithm" for infection after ankle or hindfoot arthrodesis?

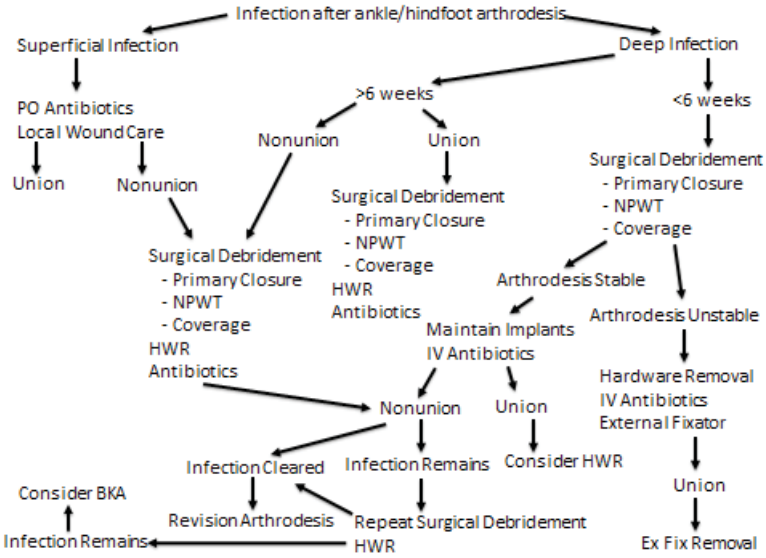
RECOMMENDATION: There is no universal algorithm for addressing the infected ankle or subtalar arthrodesis. A potential algorithm created by consensus is:

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Infection after ankle or hindfoot arthrodesis always results in a protracted recovery. Recovery from this complication may include multiple surgeries, escalating cost and may result in a painful and poorly-functioning limb. Patients with suspicion of infection following ankle or hindfoot arthrodesis should be evaluated for deep versus superficial infection as well as appropriate host and surgical factors to determine the most appropriate treatment. Superficial infections may be treated with irrigation and debridement (I&D), local wound care and pathogen-specific antibiotics. Deep infections involving the internal hardware should prompt hardware removal. Additional components of treatment may include some combination of placement of antibiotic beads or spacers, stabilization with external fixation to temporarily stabilize or achieve definitive arthrodesis [1] and delayed revision arthrodesis with internal fixa-



HWR, hardware removal; NPWT, negative-pressure wound therapy

tion following eradication of infection. The patient's nutritional and vascular status should be optimized. If soft tissue coverage is necessary, a multidisciplinary approach is necessary to determine the viability of the extremity. To achieve fusion, a radical debridement, stable fixation and minimal compromise of the marginal blood supply are necessary.

All patients should be critically evaluated in a multidisciplinary approach to optimize the patient's health and psychological status. Every effort to minimize the risk of wound breakdown should be pursued including optimization of diabetes, reduction of inflammatory conditions, the absence of tobacco use and optimal nutrition. The impact of prolonged impaired mobilization, possible unemployment and social isolation should not be neglected and may compromise patient adherence for further surgery and postoperative regimens, as well as diminish functional outcomes. We recommend an appropriate evaluation of the patient host and arthrodesis surgical factors in patients with infection following tibiotalar or subtalar arthrodesis.

Infection following ankle or hindfoot arthrodesis may significantly delay bony consolidation. Frey et al. reported as high as 60% nonunion rate following ankle fusion complicated by infection [2]. In order to address the infected ankle or hindfoot fusion, several algorithms have been proposed [1,3]. Any patient in which bony fusion is uncertain should be evaluated by computerized tomography (CT) to assess the arthrodesis. Debridement followed by arthrodesis remains the salvage procedure of choice for the infected ankle and subtalar joints, and has proven to be an effective means for limb salvage and maximizing patient functional outcome [1,3–5]. Härle reported the results of a two-stage procedure with the treatment of infection first by implant removal, thorough debridement and implantation of Septopal® (Gentamicin-PMMA chains) beads, followed by secondary internal stabilization with an antibiotic-releasing bone plate. Although 3 of the 42 patients (7%) ultimately required an amputation, infection was cured long-term in 36 (84%), and 39 (93%) achieved stable bony fusion [3]. Paley et al. recommended removal of all internal hardware and sharp debridement of all necrotic and infected tissue followed by external fixation and reported 100% union [1]. Baumhauer et al. reviewed the literature on arthrodesis of an infected ankle and subtalar joint but did not suggest an algorithm for treatment of infection after ankle or subtalar joint, arthrodesis [6].

Host Factors

Host factors must be optimized prior to undergoing reoperation. Malnutrition, diabetes and nicotine cessation should be advocated. Preoperative malnutrition has been associated with delayed wound healing [7], longer length of stay and anesthesia/surgical times [8] and failure of treatment of persistently draining wounds inevitably leading to deep infection [9]. The measures of malnutrition have varied and may be defined by a variety of methods including serological laboratory values (e.g., transferrin, total lymphocyte count, serum albumin and prealbumin), anthropometric measurements, and standardized scoring tools [10]. The most common definitions of malnutrition are total lymphocyte count (TLC < 1500/cc) and serum albumin (< 3.5 gm/dL) [9,11,12]. Frey et al. reported that patients with major medical problems including renal failure, significant smoking history, diabetes and alcohol abuse demonstrate an 85% nonunion rate following attempted ankle fusion [2]. Jaberi et al. reported successful salvage of patients undergoing hip and knee arthroplasty in only 5% of malnourished patients treated with I&D [9].

Diabetes

Perioperatively elevated blood glucose levels and complicated diabetes mellitus prior to elective surgery predispose patients to postoperative soft tissue and bone healing complications [13–18]. The current guidelines, as published by the American Diabetes Association, recommend that surgery should be avoided if possible for those patients with hemoglobin A1c (HbA1c) greater than 7% [19]. In an effort to validate the recommendation, Jupiter et al. assessed the relationship between the HbA1c levels and the rate of postoperative infection [20]. Their results indicated that infection rates increase steadily as the HbA1c increases toward 7.3%, increase rapidly at an HbA1c of 7.3% to 9.8%, and then level off. Several studies demonstrate an increased risk of infection following arthroplasty in patients

with HbA1c greater than 6.5% [20–22]. Although it is unclear in foot and ankle literature whether any specific HbA1c should serve as a contraindication for revision fusion, multiple studies have demonstrated that diabetic neuropathic arthropathy contributes to high complication and failure rates. Ankle and subtalar arthrodesis should thus be considered with caution in the diabetic patient [23].

Tobacco

All efforts should be made to eliminate exposure to nicotine and tobacco products. Studies have demonstrated that patients who smoke tobacco are at three times greater risk of hindfoot nonunion [24]. Fragomen et al. reported a 54% nonunion rate in tobacco users who smoke undergoing primary arthrodesis [25]. Patients who undergo revision are certainly at higher risk of both osseous nonunion and soft tissue complications following revision hindfoot nonunion. Although the literature is unclear, we recommend waiting at least six weeks following smoking cessation in order to reduce the risk of pulmonary complications associated with rebound mucosal secretions and increased perioperative complications associated with smoking cessation in the perioperative period. In addition, we recommend confirming cessation via testing for nicotine and its primary breakdown product (metabolite) cotinine in the blood, urine, saliva or hair. Cotinine is widely used when compared to other diagnostic tools because of its higher sensitivity, specificity and long half-life, as well as the fact that it is the best indicator for distinguishing the tobacco users from non-users. We prefer urine biomarker testing over serum given its high sensitivity compared to blood cotinine and minimally invasive collection [26,27]. We recommend a urinary cutoff of greater than or equal to 2.47 ng/ml to detect the highest sensitivity and specificity of 100% for smoking [28].

SURGICAL PROCEDURES

Irrigation and Debridement

Isolated surgical I&D should be reserved for soft tissue infections that are not in direct communication with hardware. Given the risk of persistent chronic infection following infected ankle or hindfoot arthrodesis, we do not recommend isolated I&D of the deeply infected arthrodesis. If there is any uncertainty concerning whether the retained hardware is in communication with infected tissue, the hardware should be removed given the high failure rate associated with retained hardware [1,3–5].

Soft Tissue Coverage

The overlying soft tissue must be evaluated to determine whether adequate soft tissue coverage is possible; sinus tracts may be excised and hardware remains exposed. Multidisciplinary assistance from plastic surgery may be necessary if primary or delayed primary is not possible and if the surgical site necessitates a local or free flap for closure. Commonly utilized flaps for the hindfoot may include reverse sural flap or free flap (e.g., anterolateral thigh via the circumflex femoral pedicle, superficial circumflex iliac artery perforator and thoracodorsal artery perforator flaps) [29].

Bone Stock

Viable bone must be evaluated to determine remaining available bone for reconstruction and possible salvage arthrodesis [30]. There are limited case reports of salvage tibiotalocalcaneal (TTC) arthrodesis with a custom titanium alloy truss and retrograde intramedullary nail for hindfoot infection with bone loss [31]. We were unable to identify any clear literature on the most appropriate management of the infected ankle and subtalar arthrodesis with significant osteolysis, subsidence or bone loss following excision of bone with osteomyelitis.

Explantation of Hardware

In 1999, Costerton attributed the persistence of certain chronic infections to the presence of biofilm, and since then the majority of implant-related infections in orthopaedics are believed to be biofilm-related infections associated with glycocalyx polysaccharide biofilms that are often recalcitrant to antibiotic treatment and may be culture-negative with ineffective clearance from the host [32,33]. Given the risk of biofilm-related infections, reimplantation of a prosthesis should be delayed until adequate resuscitation and eradication of the offending organism has been completed [34–44]. However, Paley et al. supported using external fixation following explantation of hardware in the infected failed hindfoot fusion [1].

FIXATION TECHNIQUES

Internal Osteosynthesis

Several techniques have been reported for utilizing plate fixation for revision ankle arthrodeses [45–49]. However, successful internal fixation following infection has only been described in the setting of the septic ankle. Klouche et al. reported the outcomes of 20 patients who underwent tibiotalar arthrodesis in the presence of sepsis with internal osteosynthesis resulting in a fusion rate of 89.5% and clearance in 85.0% of cases [50]. Richter et al. reported solid ankle or hindfoot arthrodesis following infection in 39 of 45 patients (87%) utilizing hybrid fixation with both internal (compression screws and an anterior plate) and external fixation [51].

External Fixator

TTC arthrodesis using the Ilizarov technique is a viable alternative to amputation in patients with infected nonunions or large bone loss of the tibia or talus precluding internal fixation with reported fusion rates as high as 77 to 93% [5,52–54]. Saltzman reported on eight patients with diffuse ankle osteomyelitis who were treated with resection of the infected bone and application of a compressive circular external fixator. Six weeks of intravenous antibiotics were administered and wound vacuum devices were applied over open wounds. Sepsis was eradicated in all [55]. It should be noted that these patients had the diagnosis of osteomyelitis, but not specifically an infected ankle or hindfoot arthrodesis. Similarly, Raikin recommended I&D, a six-week course of intravenous antibiotics, removal of internal hardware and stabilization of the arthrodesis with an external fixator. A vacuum device or plastic surgery coverage was recommended for an open wound [56]. For failed ankle arthrodeses, Hawkins et al. reported on 21 cases which were salvaged with the Ilizarov technique. Of the patients 80% achieved fusion and resolved infection [57]. Although external fixation is typically indicated for patients with active or previous infection, union rates and outcome measures of external fixation are inferior to internal fixation [58].

Intramedullary Fixation

Techniques utilizing an antibiotic-impregnated intramedullary polymethyl methacrylate (PMMA) nail or antibiotic-coated intramedullary nail have been described [59–61]. To achieve successful fusion in the setting of infection, it is important to not only remove any hardware with potential formation of glycocalyx polysaccharide biofilm but also to avoid introducing new foreign bodies at the site of infection, and, therefore, external fixation is often

considered the gold standard. However, antibiotic-coated intramedullary nails may also be considered if acute shortening and bone contact may be achieved [61,62]. The current literature supporting antibiotic-coated nails for the treatment of infected ankle nonunions and infected distal tibial fractures to achieve fusion, improve patient functional outcomes and successfully eradicate infection are encouraging. However, these studies are limited to small case series. Future studies are necessary to better understand the potential for union, functional outcome and infection control utilizing intramedullary antibiotic-coated nails following infected ankle or hindfoot arthrodesis.

USE OF ANTIBIOTIC-IMPREGNATED ADJUNCT

All patients with infection following ankle or hindfoot arthrodesis procedures should be administered oral, intravenous and/or local antibiotics. Consulting your local infectious disease physician may be warranted to better assess local antibiotic nomograms and assist in recommendations. Antibiotic-loaded PMMA has demonstrated to be successful in treating osteomyelitis and is commonly used for antibiotic release to the site of infection but displays variable elution kinetics and represents a potential nidus for infection, therefore requiring surgical removal once antibiotics have eluted [63,64]. Definitive treatment with an antibiotic spacer can be considered and has been reported. Ferrao et al. reported on the use of a cement spacer after deep ankle infection. Three patients underwent an ankle arthrodesis, and the remaining six underwent TAA. Most retained their cement spacers, and those who did were ambulatory with little discomfort [65]. Alternatively, antibiotic-loaded calcium sulfate beads have the benefit of serving as an osteoconductive material with time-dependent antibiotic delivery, but have been criticized for the massive amount of drainage secondary to hydrolysis-dependent antibiotic delivery [66]. The concept of local antibiotic deposition is particularly critical in poorly-perfused limbs. The use of antibiotics in bone cement or calcium sulfate biocomposites offers several advantages, including the ability to achieve high local levels of antibiotic [67], low systemic toxicity [68,69] and minimal local tissue toxicity [70,71]. The high local antibiotic levels achieved also allows for a decreased need for systemic antibiotic usage, which is especially useful in patients who are intolerant to prolonged systemic antibiotics [64].

Amputation

Surgeons making a choice between arthrodesis and amputation need to consider the clinical situation of the individual and patient preference. Amputation of the failed infected hindfoot arthrodesis may be appropriate in select cases involving non-ambulatory patients, infection resistant to aggressive debridement and antibiotics, severe bone loss or extensive osteomyelitis that precludes arthrodesis, inadequate soft tissue coverage or peripheral vascular or neurovascular injury. Severe immunocompromising states inhibit both infection eradication and wound healing and may be prohibitive for revision or may necessitate amputation. Active intravenous drug abuse may be a contraindication to salvage of the failed infected hindfoot fusion and may also indicate the need for an amputation. Contraindications to revision may apply to non-ambulatory patients or those with extensive medical comorbidity that precludes multiple surgeries.

Biophysical Augmentation

Biological supplementation has been studied in at-risk ankle unions as well as nonunions. Given the reported high rates of nonunion and malunion in primary hindfoot and ankle unions [72], it is common practice to use some biological adjunct therapy to improve the chance of fusion including bone marrow aspirate, platelet-rich plasma (PRP), recombinant human bone morphogenetic protein-2 (rhBMP-2), cancellous bone allograft, recombinant human platelet-derived growth factor (rhPDGF-BB) in combination with a ß-TCP-collagen matrix, cryopreserved cellular bone allograft, map3 cellular allogeneic bone graft and cryopreserved amniotic membrane-umbilical cord allograft [73–77]. No study has specifically evaluated the efficacy and safety of biological adjuncts in the setting of the infected ankle and hindfoot nonunion.

Various external and internal osteobiologic devices have been shown to promote healing when used in complex ankle fusion. Three commercially distinct modalities have been investigated for bone stimulation, including pulsed electromagnetic field [77,78], internal direct current [79–82] and low-intensity pulsed ultrasound [83–85]. However, no study has specifically evaluated the impact of biophysical adjuncts following infected ankle or subtalar arthrodesis and further additional randomized controlled trials are necessary before justifying their utility.

QUESTION 2: What is the optimal antibiotic (type, dose and route of administration) treatment for infections after foot/ankle fracture or fusion procedures?

RECOMMENDATION: The optimal antibiotic treatment after foot/ankle fractures or fusion should be determined based on the result of culture. In the absence of culture results, administered antibiotics should include coverage against common pathogens such as *Staphylococcus aureus*.

LEVEL OF EVIDENCE: Strong

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

The commonality in the literature when addressing infection following traumatic foot/ankle procedures or fusions is to target antibiotic therapy to the specific pathogen [1–6]. This is achieved by taking intraoperative cultures, often preceded by preoperative joint aspiration. The majority of the literature suggests a six-week course of intravenous antibiotics; however, the range of recommended therapy is five days to three months [2,5,7].

The second method for delivery of antibiotics is by the incorporation of the antimicrobial agents into the cement spacer when surgical intervention is used [1,2,8]. Since conventional cultures used to identify the infecting organism are often obtained at the time of surgery, the offending pathogen is often not known preoperatively. In this situation, or when the culture results are negative, broad-spectrum antibiotics should be administered. Vancomycin is most commonly used, not infrequently in conjunction with tobramycin or gentamycin [1,5,9].

Methicillin-sensitive *Staphylococcus aureus* (MSSA) is the most common pathogen identified with post-traumatic/post-fusion foot and ankle infections [1,4,6,10,11]. The second most common infectious organism is *Staphylococcus epidermidis* [6,12]. Multi-drug resistant organisms, such as methicillin-resistant *Staphylococcus aureus* (MRSA), are also isolated in cultures with some regularity [6,11]. Diabetic patients have some increased risk of *Pseudomonas* infections as compared to non-diabetics [4]. Importantly, rare bacteria have been identified in case reports and polymicrobial infections have been regularly reported as well [5,13].

There is great heterogeneity in those patients being treated for post-traumatic/post-fusion infection, so it is difficult to interpret outcomes with regard to recurrent infection, ambulatory status/functionality and bony union [1,2]. Stability contributes to the resolution of infection and it has been proposed that antibiotic-coated retrograde nails can also provide local antibiotic delivery [14]. Even for those patients deemed inappropriate for a return to the operating room and for those treated definitively with an antibiotic-laden spacer, independent ambulation can be reliably achieved [3].

In conclusion, we recommend that the treatment of any foot and ankle infections following fracture or fusion procedures be based on the results of the culture, whenever available. In the absence of culture results, broad-spectrum antibiotics should be used.

QUESTION 3: What is the treatment "algorithm" for infection after Achilles tendon repair/reconstruction?

RECOMMENDATION: The initial treatment of an infected Achilles tendon reconstruction should include thorough debridement of all infected tissues with the removal of retained sutures or foreign material. Cultures should be taken at the time of debridement and antibiotic administration should be dictated by the result of culture and continued until inflammatory markers and clinical symptoms normalize. If significant soft tissue defect in the overlying area remains, the choice of tendon reconstruction and/or transfer with soft tissue coverage should be left up to the discretion of the treating surgeon based on preference and expertise. Revision reconstruction should be delayed until the infection is cleared.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Infection following Achilles tendon repair/reconstruction is a potentially catastrophic complication of a relatively common orthopaedic procedure. Wound complications following Achilles tendon repair occur in approximately 10% of cases [1], although the proportion of patients requiring secondary surgery or prolonged care has been reported to be substantially lower (2.44%) [2]. The loss of Achilles tendon tissue and soft tissue coverage secondary to infection leads to poor results and can be difficult to manage [3].

The optimal treatment of an infection following Achilles tendon repair/reconstruction consists of infection eradication, maintenance or restoration of ankle plantar flexion and soft tissue coverage. A literature search for the treatment of infection following Achilles tendon repair/reconstruction reveals a heterogeneous collection of expert opinions and case reports/series on how to accomplish these goals, with no definite consensus. While the literature generally agrees that the most important aspect of treatment revolves around an extensive debridement of the infected/necrotic tissue and antibiotic coverage, each author has their own opinion on how tendon and soft tissue defects should be addressed. These opinions range from extensive debridement with functional rehabilitation alone [4,5], to local tendon/tissue transfer [6–11], to free flaps [12–17]. Additional variations of treatment include single versus staged procedures [18,19], the utilization of cement spacers [18,19], tissue expanders [19] and negative pressure wound therapy [20,21].

Given the heterogeneity of the literature and the lack of any high level of evidence publications on the subject matter, we are unable to formulate a definitive consensus statement with regards to soft tissue coverage of the infected Achilles tendon following a prior repair/reconstruction. There is, however, evidence to suggest that thorough debridement of all infected tissue with the removal of retained suture or foreign material and antibiotic administration should be the initial step in the treatment of these patients. Cultures should also be taken at the time of debridement and antibiotic administration should be culture-driven and continued until inflammatory markers and clinical symptoms normalize. If significant defects remain in the Achilles tendon and overlying soft tissue following debridement, the choice of tendon reconstruction and/or transfer with soft tissue coverage should be left to the discretion of the treating surgeon based on preference and expertise.

QUESTION 4: Should treatment of diabetic foot osteomyelitis be based on bone biopsies?

RECOMMENDATION: Yes. Bone biopsies play both a crucial diagnostic and interventional role in the management of diabetic foot infection. While bone biopsies are not required in every case of diabetic foot infection, their most important role is in guiding accurate antibiotic treatment, as they provide more accurate microbiological information than superficial soft tissue samples in patients with diabetic foot osteomyelitis.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Diabetic foot infections of the skin and soft tissue can lead to contiguous spread to underlying bone, resulting in osteomyelitis. Where a diabetic foot ulcer fails to heal with no other apparent reason or when exposure of bone is observed, osteomyelitis should be suspected. Plain radiography has demonstrated to have poor sensitivity in detecting osteomyelitis in the early stages [1].

Moreover, plain radiography and other imaging modalities do not identify pathogenic organisms, and, thus cannot guide antibiotic therapy. Despite the ease of obtaining superficial wound swab cultures, the cultured organisms are polymicrobial and do not correlate well with bone biopsy cultures and, therefore, should not be used to guide antibiotic therapies [2–6]. A single retrospective multicenter cohort study reported that the rate of infection resolution was significantly higher in the group for whom the choice of antibiotic regimen was based on bone culture versus those based on wound swab culture (82% vs. 50%, p = 0.02) [7].

Bone biopsies taken for microbiological and histopathological analysis are the gold standard for a definitive diagnosis of osteomyelitis [8–10]. A specimen can be obtained either transcutaneously through uninfected skin or as part of an operative procedure following debridement. Bone biopsies play both a crucial diagnostic as well as interventional role in the management of diabetic foot infection. While bone biopsies are not required in every case of diabetic foot infection, their most important role is in guiding accurate antibiotic treatment.

A positive microbiological result is where one or more pathogens from a reliably-obtained bone specimen is cultured [11]. It has shown to give a sensitivity of 92% and specificity of 60% in diagnosing diabetic foot osteomyelitis [12]. Reliable and accurate identification of the causative pathogens in diabetic foot infections is important, as prolonged antimicrobial therapy is tailored according to microbiological susceptibility profile. Most diabetic foot osteomyelitis cases are polymicrobial, with *Staphylococcus aureus* being the most commonly isolated pathogen (50% of cases). Other frequently isolated organisms include coagulase-negative staphylococci, *Enterobacteriaceae*, aerobic streptococci and *Pseudomonas aeruginosa* [8,13,14]. Contamination of contiguous wound colonizing flora and skin commensals may give a false positive result, whereas prior antibiotic therapy, patchy infectious involvement or inability to culture fastidious organisms may yield false-negative results [11].

Positive histological findings include aggregates of inflammatory cells (neutrophils, lymphocytes, histiocytes and plasma cells), erosion of trabecular bone, marrow changes (fat necrosis, edema, fibrosis and reactive bone formation) [11,15,16]. Other causes of inflammation may give false-positive histological results, whereas sampling errors can give a false-negative result. Histological analysis may have better sensitivity than bacteriological cultures, as the latter is often performed under flawed conditions. However, a study by Meyr et al. has questioned the statistical reliability of the histopathologic diagnosis of diabetic foot osteomyelitis using bone biopsies, quoting a 41% of clinically significant disagreement between different pathologists, falling short of what would be expected of a “reference standard” [16]. This highlights the controversy in histopathological patterns and findings that pathologists use as a reference to establish a diagnosis of osteomyelitis [15,17,18].

QUESTION 1: What perioperative antibiotic prophylaxis should be used in patients undergoing arthroscopic surgery without the use of implants or grafts? What about patients with non-anaphylactic or anaphylactic penicillin allergy?

RECOMMENDATION: The literature neither supports nor refutes the use of antibiotic prophylaxis for routine arthroscopic surgeries, without the use of implants or grafts. For non-compromised, non-implant arthroscopy, antibiotic prophylaxis is not required. Patients with comorbidities which have been shown to cause higher risk for infection may benefit from antibiotic prophylaxis. A first-generation (cefazolin) or a second-generation (cefuroxime) cephalosporin can be used as first line, including for those with a non-anaphylactic penicillin allergy. For patients with an anaphylactic penicillin allergy, other antibiotics such as vancomycin, clindamycin or teicoplanin can be used.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

The overall risk of infection following routine elective arthroscopic procedures is low (for the knee it is 0.1–3.4% [1–3] and for the shoulder it is similar at 0–3.4% [4,5]). Various patient-related risk factors that are associated with higher risk of infection have been identified including the patients being young and male, conditions resulting in immunocompromised status and history of depression [1,2]. Additional risk factors that have been identified using databases include higher body mass index, history of diabetes, longer operative time and smoking [1,2]. In these patients at higher risk of infection, special consideration should be given to the use of perioperative antibiotic prophylaxis.

In a prospective study by Qi et al. there were similar infection rates in 1,326 patients irrespective of the antibiotic prophylaxis [6]. In a randomized controlled trial (RCT) by Wieck et al., administration of antibiotics did not provide additional benefit for prevention of infection in 437 patients [7]. However, it is important to note that because of the smaller cohort size, the findings may have introduced a type II error. Similarly, a recent large database study on 40,810 simple knee arthroscopies demonstrated no association between administration of perioperative antibiotics and postoperative infection [8]. Although the rate of deep infection was lower in the antibiotic group, the difference did not reach a statistical significance.

Randelli et al. reported an infection rate of 0.16% (15 infections) in their review of a series of 9,385 shoulder arthroscopies, with a significant difference in rates between patients receiving antibiotic (0.095%) and those not receiving antibiotic (0.58%) ($p = 0.01$) [4]. Conversely, Bert et al. retrospectively analyzed 3,231 knee arthroscopies (2,780 meniscectomies) and found patients who received preoperative antibiotics had an infection rate of 0.15% compared to 0.16% in those who did not ($p = 0.59$) [9].

A recent retrospective study by Pauzenberger et al. on 3,294 arthroscopic rotator cuff repairs with implants, demonstrated a reduced infection rate from 1.54% to 0.28% in patients who received no antibiotic prophylaxis compared with those who received 2 grams of cefazolin routinely, respectively. Further, those patients who received no antibiotic demonstrated a 5.53 times higher rate of infection [10].

In elective surgery, the preferred preoperative antibiotic is a first or second-generation cephalosporin (cefazolin or cefuroxime) [11]. They are broad spectrum, cost-effective and allow newer, more expensive antibiotics to be used for more resistant organisms. Cephalosporins cover gram-positive bacteria as well as clinically important aerobic gram-negative bacilli and anaerobic gram-positive bacteria. They have good distribution in muscle, bone and synovium, achieving fast bactericidal levels after administration [11].

One placebo-controlled trial evaluating prophylactic cefazolin in 2,137 total hip arthroplasty patients showed a significant reduction in infection[12] whereas another RCT of cefuroxime compared to vancomycin and fusidic acid in 435 arthroplasty patients showed no difference in infection rate, the lack of difference may have been because of the small sample size and underpowered nature of the study [13]. Alternative first line agents are penicillins including cloxacillin and flucloxacillin [11]. In known cases of anaphylactic penicillin allergy, other agents such as clindamycin, vancomycin or teicoplanin, if available, should be considered. Clindamycin is bacteriostatic and alone has poor activity against *Staphylococcus aureus* (MRSA) so other agents (e.g., levofloxacine) may need to be coadminsitered [11]. With a non-anaphylactic penicillin allergy, a second-generation cephalosporin can still be used as there is limited cross-reactivity and penicillin skin testing can assess for a true allergy [11]. Patients colonized with MRSA should receive vancomycin or teicoplanin [14]. A recent report from Europe showed that teicoplanin was the most common agent used in high-risk patients with associated comorbidities (84% of practices), but is not available in the US, Canada or China [15].

Septic arthritis post-arthroscopy remains very rare with rates of 0.009–1.1% [16]. Despite its rarity, this complication is serious as its treatment often warrants multiple surgical procedures and prolonged antibiotic treatment, with risks of significant chondral damage and patient morbidity. Despite successful eradication of infection, the joint may develop secondary osteoarthritis and functional loss [17]. Moreover, the additional short and long-term treatment costs to the patient and hospital, is a factor to consider when using antibiotic prophylaxis [18]. However, the increasing prevalence of antibiotic resistance and the occurrence of drug-related adverse events cautions its routine use [19].

Overall, the literature on antibiotic prophylaxis for knee and shoulder arthroscopy is limited. For routine elective arthroscopy

without the use of implants or grafts in the healthy patient, there is no evidence to support the use of perioperative antibiotic prophylaxis. Antibiotics may be considered when implants are being used or when the patient has certain comorbidities which are considered risk factors for infection. A first- or second-generation cephalosporin antibiotic can be used as a first line agent, including in patients with a non-anaphylactic penicillin allergy. In patients with an anaphylactic penicillin allergy, other agents such as vancomycin, clindamycin or teicoplanin can be considered.

QUESTION 2: Should routine methicillin-resistant *Staphylococcus aureus* (MRSA) screening be in place for patients undergoing elective sports procedures?

RECOMMENDATION: Routine MRSA screening is not warranted for patients undergoing elective sports procedures. Screening may be appropriate in higher-risk patients and patients undergoing more complex procedures.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Staphylococcus aureus (*S. aureus*) is the most frequent pathogen isolated from surgical site infections (SSIs) in patients undergoing orthopaedic procedures [1]. SSIs caused by *S. aureus* can be serious and difficult to treat, often requiring debridement with removal of orthopaedic implants. *S. aureus* resides on skin surfaces and asymptomatically colonizes approximately one-third of the population, most commonly the anterior nares [2]. Multiple studies have shown that *S. aureus* nasal colonization is a significant risk factor in developing *S. aureus* SSIs [3]. *S. aureus* is also found in the throat, axilla and groin [4], as well as in eczematous skin lesions [5]. Screening for and decolonization of *S. aureus* has been shown to decrease SSI rates in a variety of surgical specialties [6], but not specifically in patients undergoing sports procedures.

In some hospitals, 57% of isolates of *S. aureus* causing orthopaedic infection are resistant to methicillin [1]. Compared to methicillin-sensitive *S. aureus* (MSSA) causing SSI, patients with MRSA SSIs have been shown to have a higher risk of morbidity, mortality and greater hospital costs [7]. Indeed, one study showed that intranasal carriage of *S. aureus* was the only independent risk factor for SSIs following orthopaedic implant surgery [8].

Most studies evaluating MRSA screening and decolonization in orthopaedic patients were performed in elective total joint arthroplasty patients [9,10]. Other studies have also included spine patients (e.g., fusion) and trauma patients [11], and many did not state the specific type of elective orthopaedic patient included. These non-specific studies often had a minimum inpatient stay inclusion criterion, which therefore excludes almost all elective orthopaedic sports surgery cases.

Our extensive search of the literature identified a study by Kim et al. that evaluated patients undergoing sports procedures who

screened 7,019 of 7,338 (95.6%) preoperatively for MRSA. They also included patients undergoing total joint replacement and spine surgery, with a minimum one-day inpatient stay, though no details on the types of cases or numbers were provided. There were 309 (4.4%) MRSA carriers, and these patients did have a significantly higher risk of SSI compared to non-MRSA carriers (0.97% vs. 0.14%, p = 0.0162). However, the rates of infection in the sports surgery group were not reported [3].

Given the significant lack of data on the efficacy and cost effectiveness of preoperative MRSA screening in patients undergoing orthopaedic procedures in general and those receiving sports procedures in particular, the routine practice of MRSA screening cannot be recommended. Rates of infection after sports surgery procedures are generally lower than rates after arthroplasty or spine procedures, suggesting that screening strategies may prevent fewer infections and be less cost-effective in sports surgery than in other orthopaedic procedures. Very limited data suggests that screening may be considered in sports patients who will be admitted for at least one overnight stay, particularly if implants are to be used [3]. Further studies are needed to evaluate the efficacy and cost-effectiveness of screening for Staphylococcal carriage (MRSA or MSSA) in patients undergoing sports surgery procedures.

QUESTION 3: What perioperative antibiotic prophylaxis should be used in patients undergoing arthroscopic surgery who are methicillin-resistant *Staphylococcus aureus* (MRSA) carriers?

RECOMMENDATION: MRSA carriers should be administered vancomycin or teicoplanin as antibiotic prophylaxis prior to arthroscopic surgery involving an implant and/or a graft or for patients at higher risk of infection.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Prevalence of MRSA colonization is increasing in some community settings, even in patients who lack traditional (or any) identifiable risk factors [1]. Surveillance studies have suggested that the colonization rate in the general population varies worldwide, with methicillin-sensitive *S. aureus* (MSSA) nasal carriers making up 20–36.4% of the population, and MRSA nasal colonization composing 0.6–6% of the population [2].

When simple arthroscopy is performed (meniscal tears, articular debridement, synovectomy and microfracture), the risk of surgical site infection (SSI) is extremely low and antimicrobial prophylaxis is not routinely recommended [3–7]. However, when arthroscopic procedures involve the use of implants, grafts, placement of several surgical incisions, prolonged operative time or knee ligament reconstruction, the SSI risk is higher than in simple arthroscopy, and prophylactic antibiotic administration may be justified [8–10]. Although the efficacy of prophylactic antibiotics in reducing SSI for major orthopaedic procedures has been proven, the role of antibiotic prophylaxis in routine arthroscopy remains controversial [3,4,11,12].

Regarding arthroplasty, some studies reveal that universal MRSA decolonization is effective in reducing the overall rate of SSIs and promoting economic gains for the health system related to the downstream savings accrued from limiting future reoperations and hospitalizations [13–15]. The American Academy of Orthopaedic Surgeons (AAOS) and Surgical Care Improvement Project (SCIP) recommend first- or second-generation cephalosporins as the prophylactic antibiotics of choice for patients who are not colonized with MRSA, with vancomycin prophylaxis reserved for those who are MRSA-colonized [16]. The addition of vancomycin or an aminoglycoside to the prophylactic perioperative antibiotic regimen results in a predicted activity of 83–97% against the most common pathogens causing SSIs [17].

Thus, based on the available evidence, it is unlikely that prophylactic antibiotics are needed for simple arthroscopic procedures

in the first instance and if the prophylaxis should be modified for patients who are MRSA carriers. In the absence of evidence, and due to the gravity of any SSI being caused by MRSA, we recommend that consideration be given to administration of vancomycin or teicoplanin as antibiotic prophylaxis prior to arthroscopic surgery involving an implant and/or a graft or for patients at higher risk of infection.

QUESTION 4: What is the best method for anterior cruciate ligament (ACL) allograft sterilization to minimize the incidence of postoperative infections and mechanical weakening of the graft?

RECOMMENDATION: The best method for ACL allograft sterilization to minimize the incidence of postoperative infection and mechanical weakening of the graft is the use of irradiation (preferably less than 1.8 Mrad). Allografts should be harvested aseptically and fresh-frozen, whenever possible.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

An exhaustive literature review of articles published in English was undertaken to identify studies related to allograft sterilization and the incidence of postoperative infections and graft failures. The search was performed across the PubMed, Scopus, and Cochrane databases as well as Google Scholar using the following search terms: "allograft sterilization," "infections and allografts in ACL reconstruction," "complications after allograft use for ACL" and "mechanical strength of allografts." Articles in languages other than English were not reviewed, nor were articles on non-human subjects. The articles included were from 1988 until March 2018, (Levels I-IV evidence) containing evidence of graft longevity, post-ACL infections, revision rates following use of allografts and other complications associated with allograft use. The Preferred Reporting Items for Systematic Reviews and Meta-Analyses criteria (PRISMA) were followed.

Septic arthritis after ACL reconstruction (ACLR) is a rare event, occurring in 0.14 to 1.8% of cases [1–3]. Several studies have demonstrated a lower rate of deep infection after ACLR using allograft compared to hamstring autograft tendons and equal possibilities with the use of bone patellar tendon bone (BPTB) autograft [4–8]. The increasing use of primary allograft ACLR during the last few decades can be explained by the fact that allograft offers several advantages such as shortening operative time, reducing postoperative pain, allowing a variety of grafts to choose from and avoiding harvest site morbidity [9–11].

However, allografts bring with them an intrinsic risk of contamination, which is why every possible effort must be made in order to lower this risk as much as possible.

The American Association of Tissue Bank (AATB) has made several rules in allograft procurement, sterilization and conservation, in order to guarantee a Sterility Assurance Level, which is the probability of failing the sterilization after the whole process, lower than $1x10^{-6}$ [12]. The possibility of human immunodeficiency virus (HIV) transmission is one in 1,667,600 [13], but it drops to 1/173,600 for non-processed allograft [14]. In fact, there are several steps that follow a rigid protocol to ensure a lower risk of disease transmission. The donor must be checked for known disease and an examination of the body is taken to control any sign of infection or intravenous (IV) drugs stigmata [15].

Further, the donor is screened by serology tests for viral infection (i.e., HIV type I – II, hepatitis B virus (HBV) surface antigen, HBV core antibody or hepatitis C virus (HCV) antibody) [16]. Nucleic Acid Testing (NAT) is the best test for screening HIV and HCV because seroconversion occurs 15 days after the first contact with the virus [16]. Blood cultures are necessary to check for bacterial and fungal infection. Aerobic and anaerobic cultures last for a minimum of 15 days, according with the AATB and the Food and Drug Administration [17]. The successive step is the tissue retrieval, which is performed in a sterile operating room with sterile technique [18]. After that, the graft is treated with a bactericidal-antimicrobial disinfection solution. At this stage, the graft cannot yet be considered sterile [15].

There are several sterilization techniques, which can be split into irradiation and chemical sterilization. The irradiation can be based on gamma ray or electron-based radiation. The gamma radiation works by generating free radicals and directly modifying nucleic acids, leading to genomic dysfunction [19]. Unfortunately, the first effect can damage the collagen and compromise the mechanical structure of the graft in terms of strength and elasticity [20,21]. A low dose of radiation (< 25 KGy) is able to kill the bacteria, but does not have a complete effect on the virus [22–25]. In reverse, a high dose of radiation (> 35 KGy) can kill viruses, but several studies showed that at this level of radiation, the mechanical proprieties of the graft are compromised [22,26,27].

Additionally, it is necessary to consider that there is no consensus about the fact that a low dose of radiation does not damage the graft. Park et al. reviewed 21 publications and found a total of 1,453 ACLR with allograft (415 low-dose irradiated; 1,038 non-irradiated) [28]. The authors found worse functional outcomes and greater rates of re-rupture in patients receiving irradiated allograft. However, in the single publications, the result was good to excellent in both groups, and not all of the functional scores favoured the non-irradiated group as the International Knee Documentation Committee score was higher in the irradiated group [28].

There are several publications suggesting that a low dose of gamma radiation does not affect the biomechanical properties of the graft [29,30]. However, other studies find the opposite [31–33].

Furthermore, other studies suggest the efficacy of radioprotective solution (i.e., propylene glycol, dimethyl sulfoxide, mannitol and trehalose) in protecting the graft from even high doses of gamma radiation [20,34].

An alternative system is electron-based radiation, which has a lower penetration (8cmH_2O vs. 30cmH_2O), and a lower time is required for the sterilization (seconds vs. hours) compared to gamma irradiation. Good results have been demonstrated if used in combination with other tissue-protective measures (i.e., low temperature or carbon dioxide) [35]. Further studies are required to fully understand the effectiveness of this method.

Chemical sterilization is another option, however, some of these processes should be avoided. For example, ethylene oxide can cause post-implantation synovitis, cysts and graft failure [36,37] and iodophor rinse followed by water is not uniformly viracidal [37].

An effective solvent is paracetic acid (PAA), which does not change the strength or elasticity of the graft [38] even if it seems to be correlated with a delay in the biological remodelling, and thus can cause a reduction in early knee stability (first three months) [39].

In the absence of any definitive evidence that addresses both the mechanical strength as well as anti-infective properties in allografts, we would propose that if an allograft is the only choice available, it should preferably be fresh-frozen, aseptically harvested and subjected to less than 1.8 Mrad of irradiation. Indeed, the majority of tissue banks use combined methods (i.e., Crylife Inc., Biocleanse, Allowash, Tutoplast process, the clearant process, etc.).

QUESTION 5: Should autograft or allograft be soaked in an antiseptic or antibiotic solution prior to implantation during anterior cruciate ligament reconstruction (ACLR)?

RECOMMENDATION: Yes, autograft tissue should be soaked in an antibiotic solution prior to implantation during ACLR.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 91%, Disagree: 9%, Abstain: 0% (Super Majority, Strong Consensus)

RATIONALE

Infection after ACLR is rare but can cause serious complications [1]. Contributing factors that may predispose to infection include diabetes, smoking, increased time of surgery and tourniquet inflation, additional or larger incisions for arthroscopic portals and the use of a drain [2].

The use of a preoperative prophylactic antibiotic has been previously established to reduce infection rates in orthopaedic surgery procedures [3]. Historically, ACL allografts have been associated with a higher risk for infection. However, a recent systematic review reported no difference in infection rates between allograft and autograft tissue for ACLR [4]. Further, hamstring autograft grafts have been reported to have a higher incidence of infection compared to both allografts and bone-tendon-bone (BTB) patellar tendon autografts [5–7].

Among the published studies, there are strong evidences that pre-soaking of hamstring grafts in topical vancomycin reduced the rate of postoperative infection when compared to intravenous (IV) antibiotics alone.

Vancomycin has been reported for its use for local antibiotic infusion into joints [8]. Vertullo et al. investigated the utility of soaking hamstring autografts with vancomycin before implementation during ACLR. In their investigation, both patient cohorts received preoperative IV antibiotics while one group additionally received a pre-soaked vancomycin graft. A statistical difference in infection rates was noted between the two patient groups as the preoperative IV antibiotic-only group reported an infection rate of 1.4% compared to a 0% rate for the group with the vancomycin-soaked allograft [9].

Pérez-Prieto et al. performed a similar study. Both patient cohorts received preoperative IV antibiotics while one group additionally received a pre-soaked vancomycin graft. However, in this series, BTB autografts were included as well. The group without vancomycin saturation of the graft had an infection rate of 1.85% while the group of patients who received systemic antibiotic prophylaxis and graft pre-soaking with vancomycin did not experience any infections (0%) [10].

Phegan et al., reporting on the use of vancomycin-soaked hamstring autografts, noted no infections in a series of 1,300 patients receiving prophylactic vancomycin pre-soaked hamstring grafts in addition to systemic antibiotics [11]. Additionally, Yazdi et al. reported using gentamicin irrigation solutions in conjunction with preoperative IV antibiotics with an infection rate of 0.57% compared to an infection rate of 2.1% in patients receiving only IV antibiotics. All patients in this series received autologous grafts [12].

Vancomycin has activity mostly against gram-positive microorganisms, while gentamicin is a broad–spectrum antibiotic targeting both gram-positive and gram-negative microorganisms [11].

Due to the high impact of literature supporting the use of soaking autograft tissue in an antibiotic solution prior to implantation during ACLR, we conclude that soaking autografts in antibiotic solution is an effective treatment in reducing infection postoperatively.

QUESTION 6: What is the most appropriate/effective sterilization method of an anterior cruciate ligament (ACL) graft dropped on the operating room (OR) floor during ACL reconstruction (ACLR)? Should the tissue instead be disposed and alternate graft acquired?

RECOMMENDATION: Rinsing the contaminated graft in a 4% solution of chlorhexidine gluconate is the most effective decontamination method in the event that an ACL graft is dropped on the OR floor. When a chlorhexidine gluconate solution is used for decontamination of the dropped ACL graft, the subsequent rates of infection are very low, suggesting that there is no need to dispose of the ACL graft.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Injuries to the ACL are among the most common injuries to the knee, with reconstruction being the preferred method of treatment when functional instability is present [1]. Autografts are frequently used for ACLR, but it has been shown that the use of autografts is associated with contamination as a result of the harvesting and manipulation process [2]. Contamination of the autograft can also occur accidentally, by dropping the graft on the OR floor or allowing it to come into contact with non-sterile surfaces. In fact, a 2008 survey showed that 75% of plastic surgeons had dropped an autograft on the OR floor at least once [3]. In 94% of those cases, the autograft was decontaminated and the operation was completed. This protocol may put the patient at risk for the development of an intraoperative infection if proper decontamination procedures are not followed. This is particularly concerning given the sheer volume of ACL autograft reconstructions done each year, which has led to a variety of case studies to attempt to identify the best method for sterilizing a dropped autograft during ACLR.

Numerous studies have shown that a contaminated autograft can be effectively decontaminated by rinsing it in a 4% chlorhexidine gluconate solution [4–8]. There is some discrepancy regarding the length of time that a graft should be rinsed in the chlorhexidine solution, with 90 seconds [8], three minutes [6,7], 15 minutes [9] and 30 minutes [4] all being recommended. Khan et al. determined that rinsing a contaminated autograft in a 4% chlorhexidine gluconate solution was the most effective decontamination technique in a systematic review of seven studies [10]. The studies included used samples from a variety of sources (fresh-frozen, autograft, cadaver) and they found that 98% of contaminated grafts soaked in chlorhexidine showed no bacterial growth [10].

Bacitracin, polymyxin B and povidone iodine were additional proposed methods of decontaminating a dropped graft, but there were conflicting recommendations regarding their use. Of note, bacitracin was shown to be highly effective in decontaminating hamstring autografts [6,7], but it did not decontaminate bone-patellar tendon-bone grafts [11]. The clinical relevance of the latter observation has not been explored further. While a povidone iodine rinse was found to be a useful method of decontamination when used on grafts dropped on the OR floor, it was ineffective on samples artificially contaminated with *Staphylococcus aureus* and *Pseudomonas aeruginosa* [12].

There is a lack of patient outcomes data and randomized control trials on the subject, as well as some discrepancy regarding the length of time a graft should be rinsed prior to implantation. However, there is agreement between numerous case studies indicating that rinsing a contaminated ACL graft in a 4% chlorhexidine gluconate solution is an effective and appropriate decontamination method.

QUESTION 7: Does the use of a tourniquet influence the incidence of surgical site infection (SSI) following arthroscopic surgery of extremity joints?

RECOMMENDATION: No. A direct relationship between use of a tourniquet for arthroscopic surgery of the extremity joints and the incidence of SSI has not been established.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

The use of a pneumatic tourniquet during arthroscopy is a popular intraoperative measure to control bleeding, improve visualization, ease surgical procedures and possibly shorten the operative time, especially in knee procedures. For several decades, various studies have suggested that tourniquet application may result in an increased risk of postoperative pain, nerve paralysis, swelling, joint stiffness and functional weakness bringing into question the value of tourniquet use [1,2]. However, two meta-analyses found no difference in functional outcomes and general complications among patients undergoing arthroscopic surgery with and without the use of tourniquet [3,4]. Therefore, the use of tourniquets remains at the discretion of treating surgeon. A survey of the American Orthopaedic Society of Sports Medicine, Arthroscopy Association of North America and Delhi Arthroscopy Society members revealed that the majority of surgeons preferred to use tourniquet during arthroscopy surgery, thus making comparison of the outcome of these patients without the use of tourniquet somewhat difficult [5].

The potential influence of tourniquet use on the risk of subsequent SSI following arthroscopic surgery is not clear. If the tourniquet use results in a higher rate of SSI, a possible mechanism could be related to the effect of ischemia on antibiotic diffusion in the bone marrow. Administration of antibiotic while the tourniquet is inflated is unlikely to allow for proper diffusion of the antibiotics to the operated extremity and the joint. Because of the latter issue, a ten-minute delay between antibiotic administration and inflation of the tourniquet is proposed to allow the antibiotic to reach the required minimal inhibitory concentration (MIC) level in the operated joint [6].

Regarding the correlation between tourniquet use and the risk of infection after joint arthroscopy, no randomized controlled trials (RCTs) with this primary outcome were found. The available high-level studies on knee arthroscopy were underpowered due to the rarity of SSI, while no meta-analyses performed a pooled analysis of SSI events following tourniquet and non-tourniquet arthroscopic surgery [3,4]. Additionally, few single-center series of knee arthroscopies analyzed the risk factors for SSI. Sherman et al. retrospectively evaluated 2,640 arthroscopies, and did not report a direct correlation between tourniquet use and postoperative complications, including infection. However, a higher risk of postoperative complications was found only in patients older than 50 years and in a tourniquet time longer than 60 minutes [7]. Reigstad et al., focusing on SSI, reported two superficial infections after 876 simple arthroscopies (0.23%), mostly after medial meniscectomies, and failed to identify a significant correlation with tourniquet use. Rather, they rather reported a higher incidence of complications in cases of prolonged surgical time [8].

Also, Vachal et al. reported six SSIs after 908 anterior cruciate ligament reconstructions (ACLR) (0.7%), identifying previous surgeries as the only significant predictor for SSI [9]. The risk of infection has been specifically investigated in two large multi-centric series of ACLR, the Multicenter Orthopaedic Outcome Network (MOON) cohort and Kaiser-Permanente registry including 2,198 and 10,626 patients, respectively [10,11]. However, they were limited to the inclusion of tourniquet use and operative time in the multivariate logistic regression. The same limitation has been disclosed in other large multi-centric cohorts involving up to 700,000 patients undergoing knee arthroscopy [12,13].

Regarding elbow, wrist and ankle joints, few studies evaluated arthroscopic procedures without the use of the tourniquet, thus solid conclusion cannot be drawn regarding the impact of tourniquet use and SSI after ankle, elbow or wrist surgery [14–17].

Based on the available literature, no direct relationship between tourniquet use and SSI has been reported. What is clear is that there is a direct link between surgical time and the risk of subsequent infection in arthroscopic surgery of extremity joints. Thus, the use of tourniquets should be subordinated to the surgeon's preference and experience, and balanced with the patient's characteristics, comorbidities and the complexity of the procedure to limit the surgical time. When antibiotic prophylaxis is planned, the tourniquet should be inflated at least ten minutes after its administration.

QUESTION 8: What strategies should be employed to minimize recurrent infection of a previously infected joint during subsequent joint reconstructive (non-arthroplasty) procedures?

RECOMMENDATION: We recommend that joints with remote or recent history of infection be aspirated and the synovial fluid analyzed for the presence of infection. The affected joint should not exhibit any clinical signs of infection such as erythema, swelling, warmth and others at the time of planned reconstruction.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Our extensive literature search did not reveal any studies specifically focusing on the prevention of recurrent infection in previously infected joints during reconstructive (non-arthroplasty) procedures. It is, however, well-established that previous septic arthritis is a risk factor for subsequent surgical site infection (SSI) and periprosthetic joint infection (PJI) [1–4]. Furthermore, different studies described the risk factors for developing septic arthritis, such as morbid obesity, tobacco use, inflammatory arthritis, chronic kidney disease, diabetes and hemodialysis [5–7]. Cancienne et al. reported in their case-control study of over 530,000 shoulder arthroscopies that prior steroid injection, revision surgery and malnutrition were independent risk factors for infection [8].

Multiple PJI and SSI risk mitigation strategies may be considered in a patient with remote or recent history of joint infection undergoing a reconstructive non-arthroplasty procedure [1–3,9,10]. These are discussed in further detail below.

- Medical optimization: Consider optimization of modifiable risk factors such as treatment of any systemic or local infection, correction of malnutrition, weight reduction in patients with morbid obesity (> 40 kg/m^2), treatment of vascular insufficiency, smoking cessation, correction of hyperglycemia and preoperative cessation of immune-modifying medications [10].
- Antibiotics: Administer prophylactic antibiotics to reduce the risk of recurrent infection. In patients with previous methicillin-resistant *Staphylococcus aureus* (MRSA) infection, the addition of vancomycin or teicoplanin as perioperative antibiotic prophylaxis should be considered [10,11].
- Skin preparation: Preoperative surgical site preparation using soap (antimicrobial or non- antimicrobial) or an antiseptic agent on the night before the operative day should be considered [2,10].
- Particle-free operating environment: While there is no definitive evidence for the efficacy of laminar air flow in non-arthroplasty surgery, the number of theatre personnel and operating room traffic should be minimized to reduce the risk of recurrent infection [10].
- Respect the soft tissue: Meticulous surgical technique, proper wound closure and an effort to reduce the surgical time may help minimize the risk of recurrent infection [10,12].
- Intraoperative wound irrigation: Copious intraoperative irrigation is considered an effective strategy to reduce the number of pathogens in the surgical wound [10].
- Wound management: Antimicrobial dressings may reduce the risk of SSI [10,13].

More recently, pre-soaking of hamstring tendon autograft in a vancomycin solution has been shown to reduce septic arthritis following ACL reconstruction. As such, we recommend soaking the autograft (and possibly allograft) in an antibiotic solution such as vancomycin when used in previously infected knees [14–17].

In the absence of specific literature related to the above question, we recommend that all measures are taken to ensure that infection in the affected joint is resolved, which includes absence of erythema, swelling and so on. In addition, the affected joint should be aspirated and the synovial fluid analyzed for signs of infection.

During the reconstruction of the previously infected joint, all available strategies for prevention of infection should be implemented.

QUESTION 9: Is the surgical management of a patient with infection following anterior cruciate ligament reconstruction (ACLR) an emergency, or can the patient be optimized prior to surgical intervention? If so, what needs to be optimized?

RECOMMENDATION: Infection following ACLR is not a surgical emergency in most cases. Sepsis associated with infected anterior cruciate ligament (ACL) requires an emergency treatment. Most surgeons agree that surgical intervention should take place without delay, on a prompt basis, preferably on the same day as the clinical presentation of an ACLR infection. The patient's condition needs to be optimized prior to surgery.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Infection following ACLR is a rare event affecting up to 2.25% of patients, but it is a serious complication [1–15]. Surgical management of ACLR infections is frequently discussed in the literature, but the timing of surgical intervention is not clearly stated in the majority of these publications [3,4,6,10–12,16–18].

A few studies have addressed the issue of timing of surgery. A study by Schuster et al. stated that the surgery should be performed on the day of admission [19]. Another study by Mouzopoulos et al. also declared that the infection should be treated without delay [20]. In a review article, Wang et al. reported a summary of various studies by stating a recommendation for immediate operative treatment [21]. Torres-Claramunt et al. also reported that the generally-accepted treatment is "arthroscopic lavage, performed as soon as possible" [22]. It is known that articular cartilage degrades rapidly and loses nearly half of its glycosaminoglycan and collagen composition in the first week of a joint infection [23,24]. Therefore, a significant delay should not be experienced in the initiation of surgical treatment in patients presenting with an infection of ACL reconstruction.

The major drawback in the literature is that almost all of the studies published on infection following ACLR have been retrospective reviews. It is well-established in these studies that infection following ACLR can rarely be a life-threatening emergency. A timely and well-planned course of action based on clinical and laboratory data and microbiological findings is recommended. Graft retention has been shown as a goal along with articular cartilage protection, so lengthy delays should be avoided [1,3,6,11,13,17,18,25,26].

A protocol for patient optimization prior to surgery has not been clearly established. Clinical examination and aspiration of the knee joint is recognized as the first step in diagnosis at initial patient presentation with a suspected postoperative ACLR infection. It is also generally reported that broad-spectrum antibiotics, preferably cephalosporins, should be started as soon as possible after joint aspiration is performed [10,12,15,16,19,20,22,27]. The antibiotics should target coagulase-negative *Staphylococcus* (CNS) and *Staphylococcus aureus*, as these are the most common infecting organisms. Antibiotic therapy should be modified as soon as culture results identify the specific pathogen and the susceptibility.

Blood tests for infectious and inflammatory markers, such as white blood cell count, erythrocyte sedimentation rate and C-reactive protein, should also be conducted on the day of presentation.

This will add to the initial clinical data and offer serial information to monitor infection eradication [19–22]. Clinical records of the patient should be reviewed to identify the nature of the prior operative procedure, type of graft, method of fixation and additional meniscal or cartilage procedures, if performed [1,4,6,15,19].

As with all surgeries, comorbidities should be medically managed. This may include better control of hyperglycemia, correction of anticoagulation, correction of anemia and other conditions that may adversely influence the outcome of surgical procedure.

Authors: Arnaldo Hernandez, Roberto Rossi

QUESTION 1: Should culture samples be taken during arthroscopic treatment of a knee joint infection? If so, how many and from which area in the joint?

RECOMMENDATION: Yes, culture samples should be taken during arthroscopic treatment of a knee joint infection. We recommend that at least three culture samples from different sites be taken.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Infections of the knee joint can occur either from hematogenous spread or directly due to local trauma or a medical intervention. Infections after an arthroscopy for anterior cruciate ligament reconstruction (ACLR) or meniscal pathology are reported throughout the literature [1–18]. Infection can also occur in healthy native knees [13,19–24]. Sending intraoperative samples of synovial fluid and tissue for microbiological analysis is commonly reported in the literature [1–12,14–24], with only one study reporting no intraoperative samples for culture [13]. Two studies described the number of samples taken during the arthroscopy [11,19]. In both of the studies, five samples were taken and sent for culture. Unfortunately, no studies described an optimal area of the joint from which to take the samples.

When considering the existing research, it can be concluded that samples should be taken during arthroscopic treatment for a knee infection. However, based on the review of the literature, no conclusion can be drawn about the number of samples.

There is more research describing the number of samples to be taken during debridement in periprosthetic joint infection (PJI). In their study on 113 PJIs, Gandhi et al. concluded that the optimal number of cultures needed to obtain a positive test result was four (specificity = 0.61, sensitivity = 0.63). Furthermore, they stated that increasing the number of samples increases specificity but reduces sensitivity [25]. In the same study, the samples were collected from representative areas of the joint, including, but not limited to, synovium, intramedullary tissue, prosthetic interface and tissue from the adjacent bone [25].

During the previous consensus meeting in 2013, it was concluded that three to six samples should be obtained intraoperatively in suspected PJI cases [26]. Similarly, other authors confirmed that three to five samples should be obtained from deep tissues during surgery for suspected PJI [27,28].

There is no agreement about the area of the joint the samples should be taken from during arthroscopic treatment of septic knee arthritis. In their review, Bauer et al. reported that the samples should be taken from the deep tissue [29]. In their systematic review, Mouzopoulos et al. suggested that during arthroscopic treatment of septic ACLR, samples for culture should be taken from multiple areas, such as synovial lining, graft, femoral and tibial tunnel [30].

Based on the available data, no definitive conclusion can be drawn on the number of samples needed and the area of the joint they should be taken from during arthroscopic treatment of septic knees. Studies based on PJI were considered, as well as literature reviewed on knee septic arthritis after ACLR. Based on this data, it may be extrapolated that at least three samples should be collected during arthroscopic treatment of knee joint infection. Furthermore, they should be taken from multiple areas of the joint: graft, synovial lining and from the femoral and tibial tunnels when present. It is reasonable to also collect samples from other areas, such as the medial and lateral gutters and the suprapatellar pouch.

Authors: Sam Oussedik, Kevin Plancher, Ilaria Morelli, Domenico Ravier, Nimit Patel

QUESTION 2: What diagnostic "algorithm" should be used to diagnose infection following anterior cruciate ligament reconstruction (ACLR)?

RECOMMENDATION: The "algorithm" to diagnose postoperative infection in patients with ACLR should include clinical presentation, serological tests including C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) and analysis of the synovial fluid aspirate including gram staining and culture.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Postoperative infections following ACLR are rare, occurring in only 0.14–5.7% of cases [1–5]. As a result, clinical studies are limited and have small sample sizes. However, the general consensus is that the clinical presentation, laboratory blood tests, (specifically (CRP) and ESR) and synovial fluid aspiration analysis are essential for the diagnosis of infection after ACLR [6–13]. Magnetic resonance imaging can detect joint effusion, synovitis, edema of adjacent soft tissues and bone marrow, bone erosions, sinus tracts and soft tissue abscesses, though this has only been reported in one study [14].

Features of the clinical presentation that raise suspicion of infection include fever, malaise, sudden change in knee pain of moderate intensity, local incision drainage, local warmth, local swelling, erythema, decreased knee range of motion and inguinal lymph node enlargement, though each of these symptoms is not present in all cases [8,11,15–17].

Laboratory blood analysis should be included in the diagnosis of infection after ACLR. Interpretation of results can be challenging, as elevated levels are routinely seen postoperatively, (typically peaking by postoperative day three), as a result of the surgical trauma [3,7,13,18]. C-reactive protein levels, which increase within six to eight hours after infection, have been shown to have the highest sensitivity and specificity. Reported average C-reactive protein levels in patients after ACLR with knee infection range from 55.8 to 203 mg/L (range, 10-400 mg/L) (normal 0-0.5 mg/L) [11,15–17]. ESR levels typically rise within 24 to 48 hours [19–21]. Average ESR values in patients with knee infection after ACLR range from 57 to 76 mm/h (range, 9-108 mm/h) in the literature (normal 1-10 mm/h) [11,13,15,17,18]. Peripheral white blood cell count has also been shown to be elevated in patients with postoperative knee infection after ACLR (9.1 to 10.8 x 109/L), though this is not a consistent finding in the majority of patients [13,15,17]. Polymorphonuclear neutrophils (average 71.7%) and fibrinogen levels (average 774.7 mg/mL) have also been assessed and shown to be elevated in patients with ACLR and postoperative knee infection [13].

Gross inspection of knee joint aspiration commonly reveals turbid, yellow-green synovial fluid.[3] Microbiological analysis of synovial fluid aspirate is the most widely studied diagnostic method for septic arthritis [1,6,8,9,19,22,23]. Analysis includes gram staining, leukocyte counts, aerobic and anaerobic cultures and antibiotic sensitivities [6,13]. Positive leukocyte counts of aspirated knee fluid in knee infections after ACLR have also been reported [average 91,000 (range 64,000 to 129,000)] [6,11]. Several retrospective studies have shown that in most cases synovial fluid bacterial cultures are positive to coagulase-negative Staphylococci (*Staphylococcus epidermidis*), *Staphylococcus aureus*, *Streptococcus non-hemolytic*, *Staphylococcus schleiferi*, *Escherichia coli* or Propionibacterium in acute septic arthrosis [6,11,13,15,17–19,23,24].

Overall, there is consensus that the diagnostic algorithm for postoperative knee infection following ACLR should include sudden change in history and presentation to include change in knee pain profile, swelling and range of motion, in addition to elevated CRP

and ESR blood laboratory test values and synovial fluid aspirate microbiological analysis, though due to the rarity of its occurrence and limited number of studies and sample size, the recommendation is only of moderate strength.

Treatment

Authors: Robert van der Wal, James Murray, Clare Taylor

QUESTION 1: Can arthroscopy be used for management of patients with acute sepsis of the native knee joint?

RECOMMENDATION: Yes. Arthroscopy can be used for treatment of acute sepsis of the native knee joint.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

An extensive literature search was conducted to identify all publications related to the use of arthroscopy for management of acute septic arthritis of the native knee. A total of 18 publications were identified for review and of these, 1 was excluded as the cohort included patients with periprosthetic joint infection. Three publications were not available despite all attempts to retrieve them. Fourteen papers were reviewed in full, including five publications reporting results from the pediatric population. There was one randomized controlled trial by Peres et al., and the remaining studies were retrospective reviews [1]. In the management of septic arthritis of the native knee, the two key points to address are successful clearance of infection and minimization of complications. The pediatric papers have been reviewed separately.

Adults:

Seven papers compared arthroscopic management with arthrotomy and two papers reported only on arthroscopic results.

Jeffe et al. described successful infection clearance at four months with one procedure in 75.8% (25/33) treated with arthroscopy and 80.9% (38/47) treated with arthrotomy. This difference was not statistically significant [2]. After further statistical analyses, failure in the arthroscopic group was associated with infection being caused by methicillin-resistant *Staphylococcus aureus* (MRSA) (five out of eight failures). Similar success rates were reported by Balabaud et al. accounting for 72% (16/21) for arthroscopy and 84% (16/19) for arthrotomy [3]. Böhler et al. reported significantly lower reoperation rates and significantly better functional outcomes in patients treated arthroscopically. They achieved clearance with one procedure in 95.1% (39/41) treated arthroscopically and 79.3% (23/29) treated with arthrotomy [4]. Dave et al., with follow-up of up to 7.2 years, reported success rates of 77.8% (28/36) with arthroscopy and 60% (6/10) with arthrotomy [5]. They found no relationship between using arthroscopy and the need for multiple procedures but they did report a statistically significant relationship between the number of hours between onset of symptoms and time to index procedure and the need for multiple procedures in the group as a whole [5].

Wirtz et al. had higher success rates, at 93% (25/27) with arthroscopy and 83% (20/24) with arthrotomy [6]. A large study by Johns et al. found a 2.6 times higher chance of needing further surgery in the arthrotomy group, although overall their success rates from the primary procedure were lower than other studies with a reported success rate of 50% (59/119) for arthroscopy and 29% (12/42) for arthrotomy [7].

These results support the use of arthroscopy as the initial treatment, and are backed up by the randomized controlled trial by Peres et al. with two-year follow-up reporting 100% (10/10) success rate for arthroscopy compared to 82% (9/11) for arthrotomy [1]. However, the small sample size, and the low rate of culture positivity (at 47.6%) raises concern that some of these patients may have suffered inflammatory conditions and were not truly infected.

Complications:

Complications other than reoperation were not uniformly reported in all papers. On univariate analysis by Bovonratwet et al., higher mortality and serious adverse events were associated with arthroscopy and higher transfusion rates and minor adverse events were encountered after arthrotomy [8]. On multivariate analysis, controlled for age and American Society of Anesthesiologists (ASA) grade, there was no statistically significant difference between the risk of all adverse events or readmission. Johns et al. [7] and Böhler et al. [4] reported median knee range of motion post-arthroscopy being statistically significantly higher, in contrast to other studies discussed above. However, they did report pain at 7 and 14 days being statistically significantly better in the arthroscopy group, and reported significantly more local warmth and redness in the arthrotomy group at 1 week.

Pediatric Cases:

In the management of pediatric patients with septic arthritis of the knee, the results from five retrospective reviews also supported the use of arthroscopy. However, positive culture results ranged from 48% to 62.5%, when documented. Johns et al. concluded that arthroscopy was more successful that arthrotomy in reducing return to theatre and regaining knee function earlier. However, on long-term follow-up (mean 6.9 years) they found no significant difference between the groups [7]. Success following the first procedure was reported in 11/11 (100%) for arthroscopy and 8/13 (61.5%) following arthrotomy [7]. The other four papers on managing pediatric patients only reported results of arthroscopy. Success rates were 54/56 (96%) from Agout et al. [9], 5/5 (100%) from Sanchez and Hennrikus [10], 15/16 (93.8%) from Ohl et al. [11] and 16/16 (100%) from Stanitski et al. [12].

Complications other than return to operating room were reported in all papers, but not uniformly. At 6.9 years of follow-up, Johns et al. found no difference between the Knee Injury and Osteoarthritis Outcome Score (KOOS) and Lysholm scores, range of movement, leg length discrepancy (LLD) and gait between the arthroscopy and arthrotomy groups [7]. At three weeks follow-up, Ohl et al. reported that all patients had resumed normal activities and

no abnormalities on radiographs [11]. Agout et al. [9], Sanchez and Hennrikus [10] and Stanitski et al. [12] reported no pain, symmetrical range of movement, no radiographic changes and < 5mm of LLD in all patients at final follow-up.

QUESTION 2: What type of lavage solution should be used in patients with a native knee infection being treated with arthroscopy?

RECOMMENDATION: We recommend that high volumes of saline without antibiotics should be used as the arthroscopic lavage solution for native knee infection.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Infection of the native knee can be treated surgically by open or arthroscopic methods [1–3]. Arthroscopic lavage techniques have been used widely, since the introduction of arthroscopic debridement offers the benefits of smaller incisions, decreased tissue damage and lower reinfection rates compared to open methods [1–3]. Arthroscopic treatment yields good to excellent results, though there are a limited number of comparative studies in the literature (many with small sample sizes) [1–10]. Irrigation aids in the removal of debris and decreases the intra-articular concentration of chondrolytic enzymes better than needle aspiration alone [11,12].

There is a general consensus in the literature supporting high-volume (10 to 15 L) arthroscopic lavage with saline combined with intravenous antibiotics both in pediatric and adult patients for septic arthritis [1,3,9,10,13–25]. Based on microbiological findings, lavage plus intravenous antibiotics appears sufficient to eradicate *Staphylococcus aureus*, the most common cause of septic arthritis of the native knee [7]. Two studies with larger patient numbers support saline irrigation without intra-articular antibiotics as the lavage solution of choice [2,7]. A large number of other studies described using saline lavage solution for arthroscopic treatment of knee sepsis, with an average volume of 10.1 L [6,9,17,18,20,22,26–30]. Shinjo et al. compared the effects of two common arthroscopic irrigation solutions on meniscus tissue cells, and demonstrated that Ringer's lactate solution better maintained human meniscus cell integrity than the isotonic saline [31].

Additionally, there is a lack of agreement on the use of intra-articular antibiotics despite their frequent use during arthroscopic treatment of infected native knees in clinical practice without recommendation, thus warranting further investigation [32,33]. While some are proponents of intra-articular antibiotics, others are concerned about resultant chemical synovitis and potential chondral toxicity, not mentioning the risk of increasing antibiotic resistance [5,34,35]. Only one study by McAllister et al. specifically described using an antibiotic-loaded Ringer's lactate solution during arthroscopic treatment of four postoperative septic knees following anterior cruciate ligament reconstruction. The antibiotic name was not mentioned, but they reported a 100% eradication rate for infection [17]. The use of continuous irrigation-suction drains with antibiotics added to the irrigation solution has been both supported and refuted in the literature [4,5,34,36–38]. Some studies support the use of continuous suction irrigation drains with saline, whereas others caution against their use due to concerns of secondary infection [2,4–7,13,14,14,14,34,36,39].

In conclusion, other than saline, there is limited data to support the use of other arthroscopic lavage fluids for treatment of native knee infections and further comparative clinical studies are needed.

QUESTION 3: Should a synovectomy routinely be performed during arthroscopic treatment of an acute infection following anterior cruciate ligament reconstruction (ACLR)?

RECOMMENDATION: No. Total or partial synovectomy should be reserved for cases of severe or chronic infection.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

According to Gaechter and the proposed classification, the synovial membrane serves as a natural barrier in infection [1,2]. As a result, a primary synovectomy should be avoided in acute infections except for later stages [1,2]. The four stages of joint infection described by Gaechter were:

Stage I: Synovitis, turbid fluid, possible petechiae

Stage II: Fibrin clots, franc pus

Stage III: Thickening of the synovial membrane (up to several centimeters), multiple pouches due to adhesions

Stage IV: Pannus. Aggressive synovitis, radiographically visible changes, subchondral erosions

Klein et al. suggested a stage-oriented therapy for the treatment of bacterial joint infections in 1989, based on three stages of infection, which largely coincided with the stages I to III according to Gaechter [3].

An extensive irrigation of the joint and removal of all hematoma, fibrin deposits and partial synovectomy should be performed when synovitis is present [4,5]. In the presence of cartilage erosions in the joint or additional septa, a subtotal synovectomy is recommended [3]. Other studies advocate for a synovectomy during the first irrigation and debridement procedure, with fair results [6,7]. Zalavras et al. reported a successful outcome following a complete synovectomy [8]. More recent papers again recommend a synovectomy only in stages III and IV [9].

Prompt recognition of an infection and intervention with irrigation and debridement alone can prevent the need to remove ligament grafts and hardware. Therefore, a synovectomy should not be routinely performed during arthroscopic treatment of an acute infection following ACLR. However, this issue has not been well studied, and further studies are needed to address the influence of synovectomy in the management of infected ACLR.

QUESTION 4: Should the graft and all hardware be removed in the treatment of patients with an acute infection following anterior cruciate ligament reconstruction (ACLR)?

RECOMMENDATION: The initial approach to an acute infection following ACLR should be arthroscopic irrigation and debridement, retention of a stable graft and hardware and intravenous antibiotic therapy.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

The incidence of septic arthritis after anterior cruciate ligament (ACL) surgery is low (0.14 to 2.25%) [1]. In acute postoperative infections, graft and hardware removal versus retention remains controversial with the goal being to eradicate the infection, preserve the articular cartilage and retain a functioning graft.

A prospective study by Abdel-Aziz et al. analyzed 2,560 ACL procedures with 24 cases of septic arthritis, with a mean follow-up of five years. In all patients, arthroscopic surgical debridement was performed (average three procedures), followed by intravenous antibiotic treatment. In all 24 cases, infection was eradicated with this protocol. No functional differences were found compared to control group according to Lysholm, International Knee Documentation Committee (IKDC) and Knee Injury and Osteoarthritis Outcome Score (KOOS) ratings [2]. Likewise, Schuster et al. reviewed more than 7,000 ACLRs, identifying a total of 36 cases of acute postoperative infections. The graft was retained in all but one case (97.2%) with a mean of 2.25 (+/-1.22 SD) procedures required to treat the infection [3].

In a meta-analysis, Kuršumović et al. reported a success rate of 85% for graft retention and infection eradication [4]. They analyzed 16 studies with a total of 147 knee infections after ACLR. Increased rates of failure were seen in cases with persistent infection requiring subsequent procedures, from 4.4% with one arthroscopic debridement, to 11.4% with two procedures, or 25% with more than three surgeries [4]. In a similar systematic review, Makhni et al. analyzed 19 studies with a total of 203 cases of septic arthritis following ACLR and reported a success rate with graft retention of 78% [5].

Wang et al. also demonstrated success after serial irrigation and debridement and intravenous antibiotics. In addition, they demonstrated a greater graft retention rate when infection was diagnosed and treated immediately (< 7 days) suggesting a crucial time constraint to treatment [1].

Therefore, the data suggests that the initial approach to acute postoperative infection after ACLR should be to attempt to retain the graft and hardware. However, there are cases in which removal should be considered, which may include presence of gross purulence, when infection is resistant to multiple irrigations and debridement, possible bony involvement of the tibia or femur and/or a non-functional graft [6,7].

QUESTION 5: How many arthroscopic procedures are reasonable for the management of an infected anterior cruciate ligament reconstruction (ACLR) prior to considering graft and hardware removal?

RECOMMENDATION: Prior to considering stable graft and hardware removal, at least two arthroscopic procedures are reasonable for the management of an infected ACLR. There is evidence for successful treatment and graft retention with further arthroscopic procedures.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Septic arthritis after arthroscopic ACLR is rare with an overall frequency to be around 1% [1–4]. However, when it does occur, it is a potentially serious event with possible sequelae of osteomyelitis, arthrofibrosis and damage to the articular cartilage leading to osteoarthritis [5–7]. Although a rare occurrence, surgeons who routinely perform this procedure are likely to encounter this complication during their career [8].

Repeated arthroscopic lavage is part of the algorithm to treat infection after ACLR [4]. The number of arthroscopic procedures necessary is guided by clinical and laboratory progression as well as organism virulence and patient-related factors such as age and pre-existent comorbidities [3,9]. In a study by Bostrom Windhamre et al., patients suffering from septic arthritis after ACLR underwent a mean of 3.7 interventions (range 1 to 11) [10]. Arthroscopic lavage was repeated if the patient had persistent fever, swelling and a C-reactive protein level greater than 50 mg/L. In a study of 90 cases of septic arthritis after ACLR conducted by Saper et al., arthroscopic irrigation and debridement was performed in 95.5% (86/90) of cases with an average of 1.51 procedures [2].

According to Abdel-Aziz et al., a median of three (range 1 to 6) repeated arthroscopic debridement and synovectomy procedures were required to eradicate infection [3]. In another study by Schulz et al., irrigation and debridement successfully treated the infection with a mean of 2.2 procedures with no recurrences of septic arthritis or bone infection [11]. Kim et al. presented 146 patients producing 111 (78.1%) positive intraoperative cultures. *Staphylococcus epidermidis* was identified in 46 knees (41.4%) with *Staphylococcus aureus* found as the second most common organism and presented in 38 knees (34.2%) with infection after ACLR [12]. This report differs from the previous general consensus that *Staphylococcus aureus* was the most commonly reported organism in ACLR infection [9].

In their study of 147 patients with infections of the knee, Wang et al. noted that coagulase-negative *Staphylococcus* (CNS) was the most common pathogen and represented 45.6% of the infections. *Staphylococcus aureus* was second most common and was reported to cause 23.8% of the infections [7]. The virulence of the infective organisms can affect the course of treatment, but the age of the patient appears to have some bearing on the outcome and the number of arthroscopic procedures required to control the infection. Mouzopoulos et al. reported that patients over the age of 25 years required, on average, 1.12 more procedures to control infection compared to patients under the age of 25 [9].

Immediate arthroscopic lavage and debridement should be followed by six to eight weeks of intravenous antibiotic therapy, and then two to four weeks of oral antibiotics. In cases of persistent infection, repeat arthroscopy is recommended, but serious consideration for graft removal should be considered [9]. In patients with a retained graft, McAllister et al. reported that an average of 2.75 procedures were needed to sterilize the knee joint [5]. Graft retention is important, as 30% of patients with the graft retained following surgery experienced knee instability compared to 65% of patients who had their graft removed [11,13]. Early diagnosis of infection is critical, as the literature has reported that infection diagnosed within seven days post-ACL reconstruction has a higher rate of graft salvage than those infections diagnosed beyond seven days post-op [7]. Furthermore, graft retention following infection after ACLR is a viable procedure with a reported overall success rate of 85% [14].

Upon reviewing the literature, it was found that at least two arthroscopic treatments are needed to control infection after ACLR and prior to graft and hardware removal. Despite the lack of randomized clinical trials, several retrospective studies have reported that arthroscopic lavage and debridement for infection following ACLR is an effective therapeutic intervention to minimize the severity of sequelae, including osteoarthritis, osteomyelitis and arthrofibrosis [5].

QUESTION 6: How many arthroscopic procedures are reasonable for the management of an infected anterior cruciate ligament reconstruction (ACLR) prior to considering arthrotomy?

RECOMMENDATION: It is reasonable to treat acute infection of the knee following ACLR with arthroscopic debridement, repeating the arthroscopy up to six times, if necessary. The use of arthrotomy in the management of infected anterior cruciate ligament (ACL) cases is not well defined.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Infection following ACLR is rare but can be a potentially devastating complication. However, if early appropriate surgical intervention is performed, the functional outcome may be comparable to non-infected cases of ACLR [1].

Historically, septic arthritis of the native knee was treated with open debridement and varying degrees of synovectomy, as described by Ballard et al. [2]. More recently, Riel et al. demonstrated arthroscopic irrigation and debridement with good results and since then, they have become a routine treatment option for an infected ACLR [3]. Several subsequent studies have described arthroscopic debridement as the initial treatment of choice for the management of septic arthritis of the knee [4].

Makhni et al. conducted a systematic review on functional outcomes following surgical treatment of the infected knee following ACLR. The studies included in the analysis demonstrated that up to six arthroscopic procedures were performed for the resolution of infection and symptoms [4].

Böstrom et al. examined outcomes following infected ACLRs. They described a standard treatment protocol of repeated arthroscopic debridements, with a mean of 3.7 procedures per patient, although the range was wide (1 to 11 procedures) in all patients [5]. Another systematic review by Saper et al. concluded that arthroscopic debridement with graft retention is an effective treatment of infection following ACLR. The mean number of arthroscopic procedures per patient in these studies was 1.5 (range, 1 to 4) [6].

Interestingly, Petersen et al. used a treatment approach according to the Gaechter classification system. In their study, they reported complete resolution of infection following ACLR in all patients without arthrotomy. For Gaechter stage I and II patients, the mean number of arthroscopic debridement's was 2.5, while in stage III patients it was 3.4. There were no stage IV patients reported [7]. Similarly, Gille et al. utilized a treatment algorithm based on the stage of infection according to Gaechter [8]. In patients with stage III or IV infections, medial and lateral arthrotomy with near total synovectomy was performed after initial arthroscopy.

Torres-Claramunt et al. reported mean of 1.3 (standard deviation = 0.6) arthroscopic debridements in their study, and one patient required three procedures. The authors recommended repeated arthroscopic debridement, usually after 48 to 72 hours, if clinical and laboratory parameters do not improve [9]. Abdel Aziz et al. examined 24 patients with an infected ACLR, who required between 1 and 6 arthroscopic debridements before achieving complete resolution of infection [10].

The literature on the number of arthroscopic procedures needed prior to arthrotomy for an infected ACLR is sparse. Nevertheless, studies have shown that repeated arthroscopic procedures can give good results, although the number of procedures required varies. As a consequence, there may be no need to treat an infected ACLR with arthrotomy in most cases. However, in more severe and neglected cases (Gaechter stage IV), arthrotomy should be considered after initial arthroscopic evaluation of the joint.

QUESTION 7: What is the optimal duration of antibiotic treatment after surgical debridement of an infected anterior cruciate ligament reconstruction (ACLR)? Should this be altered when autograft or allograft is retained?

RECOMMENDATION: Following surgical debridement of an infected anterior cruciate ligament (ACL), antibiotic treatment should be administered for four to six weeks and can be discontinued upon resolution of clinical signs and normalization of laboratory parameters. The available literature does not differentiate between retention or removal of autograft or allograft.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

ACLR surgery is an anatomically complex procedure with high success rates and low infection rates [1–3]. Nevertheless, the onset of an infection after reconstructive ACL surgery is a devastating complication that can cause, in a short period of time, a progressive degeneration of the articular cartilage, graft failure and loss of function of the knee [1–3]. A prompt diagnosis and correct management might reduce or even prevent these unfavorable outcomes [4]. The incidence of infection following ACLR ranges from 0.14% to 1.8% [5–8].

Arthroscopic debridement followed by antibiotic treatment is the preferred therapeutic approach in aiming to control the infection and save the graft. Indeed, satisfactory functional outcomes are achieved in several cases of septic arthritis following ACLR with a graft salvage rate of about 85% [9]. However, persistent infection, despite multiple arthroscopic debridements, requires graft removal and subsequent ACL revision surgery at a later stage [9]. The duration and the route of administration of antibiotic therapy, in particular when to switch from intravenous (IV) to enteral administration, remain controversial [4].

Even though the duration of antibiotic treatment can vary between 4 and 14 weeks, most authors agree that it should be administered for no less than 6 weeks [4,10–12]. IV administration is preferable for the first two to three weeks [3,8,13]. However, the microorganism cultured and the antibiogram together with the postoperative clinical and laboratory parameters dictate the precise duration of antibiotic treatment [14].

In a systematic review, Wang et al. [15] evaluated 17 articles that fulfilled the inclusion criteria of septic arthritis following ACLR. The authors found that the arthroscopic debridement with graft retention and IV antibiotics was the treatment of choice for infected ACLR in most studies, with delayed diagnosis and treatment being the greatest risk factors for graft removal and articular cartilage damage. Indeed, out of 176 patients included in all the studies, 86.9% (153/175) underwent arthroscopic debridement for septic arthritis. IV antibiotics were continued for an average period of 29.7 days [15]. IV antibiotics for an average of four to six weeks was recommended, which might then be changed to oral antibiotics as soon as the C-reactive protein (CRP) levels drop to nearly normal values (< 1 mg/mL) [3,10,11]. Oral antibiotics were then administrated for at least another 14 days until the CRP returned to normal [15].

Out of 176 patients present in all studies, 18.75% (33/175) underwent graft removal, but the optimal duration of antibiotic treatment was not clearly reported. In two studies, the revision surgery was performed 12 months or later after the infection had resolved [16,17]. However, in another study by Burks et al. the revision ACLR was performed within six weeks after the completion of the antibiotic therapy and after the laboratory values had returned to normal [18].

Mouzopoulos et al. [19] proposed the basic management protocol with graft retention based on IV antibiotic therapy over at least four weeks followed by oral antibiotic for two to four weeks. An extended IV antibiotic therapy was given only in patients who needed more arthroscopic lavages. However, the therapeutic management in case of graft removal or retention is not well distinguished.

Gobbi et al. [20] stated that serial arthroscopic lavages and IV antibiotics with graft retention remain the most effective treatment protocol, starting with empirical therapy at the time of presentation. IV antibiotics switch to culture-sensitive oral antibiotics as soon as the CRP levels have nearly normalized (< 1 mg/mL) for six weeks, or until normalization of clinical and laboratory parameters. The average duration of IV antibiotics ranges from 17.3 days to six weeks, followed by oral administration for up to 3.2 months [2,3,7,8,11,13,21–23].

Shuster et al. [24] created a detailed treatment algorithm in which the graft is preserved as long as possible. However, graft removal is considered in persistent infections after multiple revisions, in loosened fixation or in graft insufficiency. In patients undergoing debridement and irrigation, a chain of antibiotic (gentamicin) loaded beads was inserted, protruding through the wound to allow stepwise removal within approximately one week. Empiric antibiotic therapy (cephalosporin I or II combined with an aminoglycoside, clindamycin or rifampicin) is started and antibiotic treatment is re-evaluated every day and changed according to microbiological testing, if necessary. When patients show clinical

improvement over five to six days with consistent and substantial decreases in CRP levels, they are discharged with oral therapy and weekly follow-up examinations. The duration of antibiotic therapy is based on the individual course of each patient and antibiotic therapy is terminated when CRP levels are within normal range (< 5 mg/L) [25]. The mean duration of inpatient treatment was 16.5 ± 8.2 days (range, 4 to 45 days). The mean duration of antibiotic treatment was 5.4 ± 2.3 weeks (range, 2.1 to 12.9 weeks). In 13 patients (36%), the duration of antibiotic treatment was < 4 weeks. A maximum of two arthroscopic irrigation and debridement procedures (mean, 1.46 ± 0.52) was necessary for eradication of the infection in these patients [25].

The available evidence does not allow for drawing a conclusive recommendation regarding the optimal duration of antibiotic treatment after surgical debridement for infected ACLR. However, the literature suggests that antibiotic treatment should be followed for four to six weeks and continued until clinical conditions are improved. Moreover, the literature is still controversial on the duration of antibiotic treatment in case of graft and hardware retention or removal, focusing mainly on the former case. Furthermore, most of the authors do not differentiate between autograft and allograft, considering and treating them in the same manner.

QUESTION 8: Should the rehabilitation protocol be modified after surgical debridement of an infected anterior cruciate ligament reconstruction (ACLR)? If yes, what changes should be made with regards to range of motion and weightbearing status?

RECOMMENDATION: We recommend that rehabilitative treatment after surgical debridement of an infected ACLR with graft retention should not differ substantially from primary reconstruction; it should be focused on preventing stiffness and regaining motion through passive and active-assisted range of motion exercises before progressing.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

The development of an infection after ACLR can have significant complications including loss of articular cartilage, graft failure and loss of knee function [1–3]. Although there is wide agreement that treatment must be initiated as early as possible, several different treatment algorithms have been proposed [4–7]. With regards to the postoperative treatment, there are no studies directly focusing on rehabilitation protocols.

While it is well-established that a graded knee-strengthening program (including quadriceps and hamstrings strengthening) has to be started within the first postoperative days [4,8–11], there is no agreement regarding weightbearing status and range of motion parameters.

Rehabilitative treatment after surgical debridement of an infected ACLR does not differ substantially from primary reconstruction. It should be focused on preventing stiffness and regaining motion through passive and active-assisted range of motion exercises.

There are no studies suggesting an altered rehabilitation protocol in the setting of a postoperative infection. Monaco et al. [10] suggest the use of a brace locked in extension for two weeks, followed by a progressive increase in the range of movement and muscular strength. Alternatively, many authors allow immediate full range of movement under the supervision of a physical therapist [7,11]. Indelli et al. [12] and Wang et al. [3] recommend starting rehabilitation only after complete resolution of symptoms, and suggest only passive motion of the knee and the ankle in the meantime.

There is a lack of consensus on weightbearing status after treatment of an ACL infection. Torres-Claramunt et al. [4,13] suggest starting a strengthening program two weeks after surgery with progressive weightbearing after symptoms decrease. Likewise, weightbearing was gradually increased until resolution of symptoms in the rehabilitation protocol developed by Hantes et al. [14]. However, McAllister et al. [15] and Schub et al. [16], suggest beginning the weightbearing six weeks after surgery.

Overall, there is a lack of evidence to support a standardized approach to rehabilitation after the surgical debridement of an infected ACLR. High-quality controlled trials are needed to provide guidelines for this rare and difficult complication.

QUESTION 9: When can patients safely undergo revision anterior cruciate ligament reconstruction (ACLR) following treatment for prior infection?

RECOMMENDATION: It is considered safe to perform a revision ACLR following completion of successful treatment for infection and normalization of clinical and laboratory parameters upon resolution of the infection. The literature does not suggest a specific timeframe following resolution of the infection prior to performing revision ACLR.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 92%, Disagree: 0%, Abstain: 8% (Super Majority, Strong Consensus)

RATIONALE

Infection following ACLR is rare, with a reported incidence of 0.14% to 2.25% [1,2]. When infection does occur, there are potentially significant consequences, particularly regarding patient outcomes [3]. Following allograft ACLR, there is a well-known risk of disease

transmission, although a recent literature review found no difference in infection rates between autograft and allograft ACL reconstructions [4,5].

Graft retention following an infected ACLR is a viable option, as a recent meta-analysis and systematic review reported a success rate of 85% [2]. Matava et al. surveyed 61 orthopaedic surgeons and found that graft removal was not popular as the initial treatment, with only 6% and 33% of respondents removing the autograft and allograft following ACLR infection, respectively. However, in cases of persistent infection, 36% of surgeons removed the graft as part of their treatment regimen [6]. The same survey showed that the most common time frame for revision surgery was a minimum of 6 to 9 months (range, 3 to 15 months) after eradication of the infection [6].

Despite successful outcomes with graft retention, graft removal and revision ACLR remains the preferred method for some surgeons following infection [7]. In a retrospective review, Burks et al. reported on 8 infections out of 1,918 ACL reconstructions. Seven of these were treated with immediate irrigation and debridement with subsequent graft removal and administration of intravenous antibiotics for six weeks. Of those, four successfully underwent revision ACLR at a mean of three weeks (range one to six weeks) after completing antibiotic treatment [7]. In another systematic review and expected value decision analysis of 19 studies, revision ACLR, within 3 to 6 weeks after the infection, was shown to have promising results [8]. Gille et al. prospectively studied 31 patients with ACL infection where the graft was salvaged in 8 patients (26 %) and removed in 12 patients (39 %). Only two patients underwent revision ACLR at six and eight months post infection [9].

Williams et al. reported on 2,500 ACLRs with 7 infections: the graft was removed in 4 cases. One of these cases underwent successful revision ACLR one year later [10]. In a retrospective review of 3,500 ACL reconstructions, Indelli et al. identified 6 infections treated with arthroscopic debridement of which 2 grafts were removed, culminating in 1 revision ACLR and 1 total knee arthroplasty (TKA) a year later [11]. Furthermore, another study reported one patient treated with initial graft removal and successful revision ACL surgery one year after treatment [12]. Zalavras et al. also described a series of five infected ACL reconstructions treated with radical debridement and graft removal. Two patients had further procedures: 1 revision ACL reconstruction 14 months later and 1 TKA nine months later [13].

Hantes et al. reported 7 infected cases in a series of 1,242 ACL reconstructions. One patient did well with irrigation and debridement and six had a recurrence of infection, requiring subsequent graft and hardware removal. These patients were offered subsequent revision ACLR and graft reimplantation three months after the last operation. Four of the six patients underwent revision with ipsilateral bone patellar tendon bone autograft at an average of five months (range four to nine) post eradication of infection. The authors recommend revision ACLR after eradication of the infection for at least three months, with normal knee motion, no knee effusion and normal laboratory values [14].

Despite the lack of randomized clinical trials, there are several retrospective studies with low numbers of revision ACLR following treatment for prior infection. There is no consensus on the appropriate timing of revision reconstruction, with a reported range of three weeks to over a year. In general, it seems appropriate to delay surgery for a minimum of six weeks, but waiting three to six months post-eradication of infection may be optimal. Importantly, criteria such as normal knee motion, lack of knee effusion and normal laboratory markers must be considered before proceeding.

PART VII

ONCOLOGY

Prevention

1.1. PREVENTION: ANTIBIOTIC PROPHYLAXIS

Authors: Christina Gutowski, Michelle Ghert, Qiaojie Wang

QUESTION 1: Is there a correlation between operative time and the risk of subsequent surgical site infection/periprosthetic joint infection (SSI/PJI) in patients undergoing tumor resection and endoprosthetic reconstruction? If so, should postoperative antibiotics be prolonged in these patients?

RECOMMENDATION: Based largely on the arthroplasty literature, there is considerable evidence that prolonged operative time is associated with an increased risk for postoperative infection. However, there is insufficient evidence to suggest that a prolonged postoperative antibiotic regimen can mitigate this risk. Therefore, there is no evidence to support prolonged postoperative antibiotics in orthopaedic oncology patients undergoing surgeries of prolonged duration. If the duration of the procedure exceeds two half-lives of the prophylactic antimicrobial, intraoperative redosing is needed to ensure adequate serum and tissue concentrations of the antimicrobial.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

A thorough literature search was conducted using PubMed, Google Scholar and the Cochrane database. Search terms included "infection," "surgical duration," "surgical time," "operative duration," "orthopaedic," "resection," "reconstruction," "endoprosthesis," "antibiotic duration" and "postoperative antibiotic" in various combinations. The majority of articles found did not specifically focus on orthopaedic oncology patients.

Several studies support the hypothesis that prolonged surgical time was associated with increased risk of postoperative SSI. In a systematic review conducted by Cheng et al. [1], 4343 studies initially identified were narrowed down to 81, many of which demonstrated nearly double the infection risk in cases that exceeded cutoff times of 1-4 hours, and almost threefold the risk in surgeries exceeding 5 hours. When all included studies were pooled, the authors observed the risk of SSI to increase by 5% for every 10 minutes of surgery, 13% for every 15 minutes, 17% for every 30 minutes, and 37% for every 60 minutes. Based on the seven orthopaedic-specific studies included in their review, they found a statistically significant association between operative duration and infection with an 84% increased likelihood of SSI when operative time exceeded different cut-off points ($p = 0.0003$).

In the arthroplasty literature, although some articles have demonstrated an association between prolonged operative time and increased risk of postoperative infection, it remains controversial whether increased operative time is an independent risk for SSI/PJI. Previous studies using administrative or registry databases have linked increased operative time to periprosthetic infection after total joint arthroplasty (TJA) with statistical significance [2–6]. However, the findings of these studies were limited by the significant heterogeneity of their samples and varying definitions for PJI as well as the definitions for operative time. Using data from a single institution, Peersman et al. [7] observed the risk of infection to increase significantly in total knee arthroplasty if the surgery took longer than 2.5 hours. They also investigated the impact of 24 vs. 48 hours of postoperative antibiotics on mitigating this increased risk and found no difference in the two antibiotic regimens. An epidemiological study of over 2,000 patients who underwent orthopaedic surgery in China also demonstrated that surgical time longer than three hours was an independent risk factor for development of SSI, with an odds ratio of 3.633 [8]. Pulido et al. corroborate these findings, showing that on univariate analysis longer operative time had statistically significant association with periprosthetic infection in 9,245 hip and knee replacement patients, but multivariate analysis adjusted for confounding factors revealed that operative time was not an independent predisposing factor for PJI [9]. In contrast, there are studies that failed to demonstrate such a correlation and even found an inverse relationship between operative time and PJI [10–14].

In the orthopaedic oncology patient, risks are even higher considering that patients are often immunocompromised and tumor resection can create a large dead space contributing to development of infection. The overall incidence of SSI in cases of malignant musculoskeletal tumors is reported as greater than 12% in some studies [15] and approximately 10% according to a large systematic review and meta-analysis [16]. Nagano et al. [15] demonstrated in their series of 457 patients with benign or malignant musculoskeletal tumors that duration of surgery is a significant risk factor in acquiring SSI (using threshold of 355 minutes), with an odds ratio of 6.06. Li et al. [17] reviewed a series of 53 patients with osteogenic sarcoma who underwent resection and segmental replacement, demonstrating a postoperative infection rate of 7.5%, much higher than primary arthroplasty. They utilized an antibiotic regimen consisting of three days of intravenous antibiotics followed by five days of oral antibiotics for all of the patients, and the authors were unsure whether this made a meaningful difference. In patients undergoing allograft reconstructions, the infection rate is also high: Tann and Mankin demonstrated a 9% infection rate in their series with the duration of the operative procedure to significantly increase the infection rate [18].

Surgeons have attempted to mitigate infection rates in high-risk patients by administering postoperative antibiotics for a prolonged period; largely, the efficacy of this strategy is not borne out in the literature. Aponte-Tinao et al. [19] report an overall infection rate of 9% in their series of 673 patients who underwent massive allograft reconstruction after tumor resection. Interestingly, a longer period of postoperative antibiotics was found to be a risk factor in development of infection. In the arthroplasty literature, there has also been no benefit associated with prolonged postoperative antibiotic use: Nelson et al. [20] argue that the optimal duration of antibiotics after surgery is 24 hours, as the risk of SSI did not decrease in their randomized controlled trial comparing that to a 7-day regimen. International Consensus Meeting on Periprosthetic Infections in 2013 recommended the use of 1 dose preoperatively and 24 hours of coverage postoperatively [21]. Although the Centers for Disease Control and Prevention recently released their 2017 Guideline for the Prevention of Surgical Site Infection [22], which recommends against the use of postoperative prophylactic antibiotics, including patients undergoing total joint arthroplasty, the American Association of Hip and Knee Surgeons (AAHKS) does not agree with this recommendation [23]. At this time, the AAHKS recommends postoperative antibiotics be continued for 24 hours and supports further research to determine whether shorter duration antibiotic treatment is safe and effective. Both the Board of Counselors and Board of Specialty Societies of the AAOS have endorsed this AAHKS recommendation through an advisory opinion; the American Academy of Orthopaedic Surgeons' Board of Directors adopted that advisory opinion in June 2017 [23]. In their comprehensive publication of clinical practice guidelines for antimicrobial prophylaxis in surgery, Bratzler et al. [24] recognize that duration of surgery is a risk factor for SSI but maintain the recommendation that the duration of postoperative antibiotics for orthopaedic procedures should be less than 24 hours. In cardiothoracic procedures in particular, the exception is made for a recommendation of up to 48 hours. Orthopaedic oncology patients undergoing prolonged surgical resection and reconstruction are not listed as an exception, despite their increased risks as outlined above. An ongoing large international randomized controlled trial, the Prophylactic Antibiotic Regimens in Tumor Surgery (PARITY) has published its feasibility pilot [25] and is scheduled to complete enrolment of 600 patients by the end of 2019 (NCT01479283). The study will determine if five days of postoperative antibiotics reduces infection rates compared to one day of postoperative antibiotics in the orthopaedic oncology population.

Although a longer period of postoperative antibiotics is not recommended by the guidelines [22–24], intraoperative redosing is needed to ensure adequate serum and tissue concentrations of the antimicrobial if the duration of the procedure exceeds two half-lives of the antimicrobial or there is excessive blood loss (i.e., > 1,500 mL). The redosing interval should be measured from the time of administration of the preoperative dose, not from the beginning of the procedure.

QUESTION 2: Should factors like preoperative radiation, soft tissue vs. bone resection, presence of metal vs. structural allograft and other factors influence the dose and duration of antibiotic prophylaxis?

RECOMMENDATION: Unknown. Evidence and guidelines directing the prescription of prophylactic antibiotic regimens in musculoskeletal tumor surgery are lacking. Although long-term antibiotic prophylaxis may decrease the risk of deep infection, there is not sufficient evidence to recommend the use of anything other than routine antibiotic prophylaxis for patients undergoing major reconstruction.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Limb salvage and reconstruction using endoprostheses or bulk bone allografts have become standard of care for the management of bone tumors. In order to minimize peri- and postoperative risk for periprosthetic joint infection (PJI) development, antibiotic prophylaxis is routinely administered. While standard guidelines for primary total joint replacements exist and are widely accepted, there are no such guidelines/recommendations for reconstruction using endoprostheses or bulk bone allografts in orthopaedic tumor surgery. As a result, various opinions and variations exist between surgeons on the prescription of prophylactic antibiotic regimens in tumor surgery [1].

Duration of antibiotic prophylaxis remains one of the most important issues. For primary total joint replacement, consensus exists in that, postoperative antibiotics should not be administered for greater than 24 hours after surgery. However, oncologic patients represent a heterogeneous population which significantly differs from population of patients that undergo primary joint replacement, and different antibiotic regimes may be necessary.

There is considerable variation in the antibiotic regimens reported by available studies. Only seven studies specified the dose (i.e., 1 gm) and/or the type of prophylactic antibiotics administered (i.e., first-, second-, or third-generation gram-positive cephalosporin) [2–8]. Two studies specified giving additional coverage against gram-negative bacteria as well [5,6]. Twenty studies reported postoperative antibiotic regimens. These studies were subdivided into short-term regimens (0 to 24 hours of postoperative antibiotics) [2,3,7,9–12] and long-term regimens (greater than 24 hours of postoperative antibiotics) [4–6,8,13–21] and compared.

Several attempts were made in order to address this issue. A systematic review reported by Racano et al. (analyzing 4,838 patients included in 48 Level 4 studies) suggests that long-term antibiotic prophylaxis (pooled weighted infection rate 8%) is more effective than short-term prophylaxis (pooled weighted infection rate 13%) at minimizing infection in patients with lower extremity long-bone tumors that require surgery and endoprosthetic reconstruction [22]. Authors recognize limitations of the study, such as inconsistency in antibiotic prophylaxis used in each study, inconsistency in reporting applied regimens (only seven studies specified the dose and/or the type of antibiotics administered), majority were retrospective studies, and it was unclear whether the definition of infection is constant in all studies, since criteria changed over time [22]. These findings are important for two reasons. First, they support the notion that orthopaedic oncology patients are diverse populations who may require a diverse prophylactic regimen when compared to conventional arthroplasty patients. Second, these results reinforce the increasing need to limit infections and establish guidelines for antibiotic prophylaxis in tumor surgery.

In contrast, Aponte-Tinao concluded that prolonged periods of postoperative antibiotics were associated with a greater risk of infection. Other risk factors associated with increased infection rate were tibial allograft, male patients and procedures performed in conventional operating room [23].

Currently, there is an ongoing multicenter randomized controlled trial titled Prophylactic antibiotic regimens in tumor surgery (PARITY). This study includes a parallel two-arm design to investigate whether a 24-hour (short) or 5-day (long) antibiotic prophylaxis regimen should be implemented among patients undergoing surgical excision and endoprosthetic reconstruction of lower-extremity primary bone tumors [24]. The primary outcome is the rate of deep postoperative infections in each arm. Secondary outcomes include type and frequency of antibiotic-related adverse events, patient functional outcomes and quality-of-life scores, reoperation and mortality. Patients will be followed for one year after the procedure. The results of the final study are expected soon [25].

Unfortunately, there is insufficient literature to support alternate antibiotic regimens in patients who underwent preoperative radiation, patients who underwent soft tissue or bone resection, or patients who received a metal endoprosthesis or structural allograft after tumor resection. The main reason is poor reporting of the antibiotic regimens (dosage, duration, etc.), and therefore, all conclusions may be misleading. Even if this data were available, it would not be accurate to properly compare the infection rates of different clinical series based on their perioperative antibiotic protocols because of the heterogeneity of patient populations.

Since data on prophylactic antibiotic regimens are rather scarce, high quality, randomized controlled trials are needed for oncologic endoprosthesis or bulk bone allograft reconstructions in tumor orthopaedic surgery. As a result, the strength of the recommendation is limited.

QUESTION 3: Should patients with an oncologic endoprosthesis in place receive antibiotic prophylaxis during dental procedures?

RECOMMENDATION: Not routinely. Evidence-based guidelines by dentists and orthopaedic surgeons state that antibiotic prophylaxis is rarely appropriate for patients with prosthetic joints.

LEVEL OF EVIDENCE: Consensus.

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

The American Dental Association (ADA) [1] and the American Academy of Orthopaedic Surgeons (AAOS) [2,3] have issued updated guidelines regarding the need for antibiotic prophylaxis. The guidelines do not specifically address the topic of patients with an oncologic endoprosthesis. The guidelines are based on four case-control studies [4–7] that found no association between dental procedures and PJI and no effectiveness for antibiotic prophylaxis.

The ADA recommended that, "in general, for patients with prosthetic joint implants, prophylactic antibiotics are not recommended to prevent prosthetic joint infection." Likewise, the AAOS recommended that "the practitioner might consider discontinuing the practice of routinely prescribing prophylactic antibiotics for patients with hip and knee prosthetic joint implants undergoing dental procedures." The AAOS recommendations were more conservative than the ADA recommendations. The AAOS conducted a study using a modified Delphi procedure in which 14 experts were given scenarios involving patients with prosthetic joints and voted whether antibiotic prophylaxis was appropriate. The panel concluded that prophylaxis may be warranted in the following situations: procedures involving manipulation of the gingival tissue or periapical region of teeth or perforation of the oral mucosa in patients who are severely immunocompromised and (1) have uncontrolled diabetes (glucose > 200 mg/dl, $HbA_1C > 8\%$), or (2) have controlled diabetes (glucose < 200 mg/dl, $HbA_1C < 8\%$) and have a history of periprosthetic joint infection (PJI) that required surgery or (3) do not have diabetes and have a history of PJI that required surgery and the initial joint replacement surgery was < 1 year ago.

The Dutch Orthopaedic and Dental Societies issued guidelines based on nine studies, all deemed to be very low quality. These guidelines advise that antibiotic prophylaxis should not be given to prevent PJI, regardless of the patient's immune status.

Given the absence of studies in patients with an oncologic endoprosthesis, it seems prudent to apply the more moderate AAOS guidelines to this patient population.

QUESTION 4: Should prophylactic antibiotics be started in patients with an oncologic endoprosthesis who develop neutropenia secondary to postoperative chemotherapy?

RECOMMENDATION: Not routinely. Evidence-based guidelines recommend limiting the routine use of prophylactic antibiotics to high-risk patients with chemotherapy-induced neutropenia.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Guidelines published by the Infectious Diseases Society of America (IDSA) and the National Comprehensive Cancer Network (NCCN) recommend the use of fluoroquinolone prophylaxis during neutropenia in high-risk patients [1,2]. Risk stratification is based on a number of criteria, including malignancy type. According to IDSA guidelines, "Low-risk patients are those with neutropenia expected to resolve within 7 days and no active medical co-morbidity, as well as stable and adequate hepatic function and renal function. These low-risk features are most commonly found among patients with solid tumors" [1].

These recommendations are based on meta-analyses which included predominantly patients with hematological malignancy [3–5]. None of the articles included in the meta-analyses examined antibiotic prophylaxis in patients with primary bone malignancy or patients with an oncologic endoprosthesis. Furthermore, none of the articles specifically addressed cancer patients with foreign bodies. The largest and most comprehensive of the meta-analyses found that antibiotic prophylaxis reduces overall mortality versus placebo, with a number-needed-to-treat of 34 and low heterogeneity [4].

Two reasons limit the use of antibiotic prophylaxis in low-risk patients. First, concerns exist regarding the development of bacterial resistance and subsequent infection [2]. Although a meta-analysis found that fluoroquinolone prophylaxis leads to a non-significant increase in colonization with resistant bacteria with no difference in infections due to resistant bacteria, concerns remain [6]. Second, guidelines recommend treating low-risk patients with neutropenic fever as outpatients, with oral antibiotics including fluoroquinolones on an outpatient basis. It is unclear whether the potential benefit of prophylactic quinolone use is greater than that of the use of these agents as treatment [2,7]. In summary, given the evidence to date, patients with an oncologic endoprosthesis should not routinely receive antibiotic prophylaxis during neutropenic episodes.

QUESTION 5: What type, dose and duration of prophylactic antibiotic(s) should be administered to patients undergoing oncologic endoprosthetic reconstruction who have received or will be receiving chemotherapy and/or radiation?

RECOMMENDATION: Antibiotic prophylaxis should be given in accordance with existing guidelines for standard arthroplasty surgery and other orthopaedic surgical procedures with foreign body placement.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 93%, Disagree: 0%, Abstain: 7% (Super Majority, Strong Consensus)

RATIONALE

Studies examining the effect of chemotherapy and radiation on risk of postoperative infection in tumor patients have found an increased risk of surgical site infection (SSI) following radiation therapy (thoracic, head and neck, gynecological, breast malignancies) and chemotherapy (thoracic, head and neck, breast malignancies) [1,2]. No studies have been conducted to compare different prophylactic antibiotic regimens for patients who received radiation or chemotherapy prior to surgery; in a single randomized, controlled trial comparing prophylactic antibiotics with placebo in breast cancer patients, no significant difference was seen in the risk of developing postoperative infection between patients who received neoadjuvant chemotherapy and those who did not [3].

Studies examining the effect of chemotherapy and radiation on risk of postoperative infection specifically in patients with bone tumors and metastases have shown differing results based on the type and location of disease. A study of patients who underwent a variety of lower-extremity oncological operations did not find either chemotherapy or radiation to increase the risk of infection [4]. Similarly, in a cohort of patients undergoing surgery for primary bone tumor, mostly involving the lower limb, chemotherapy was not a risk factor for infection, nor was it in a group of patients who underwent endoprosthetic reconstruction for tumors around the knee [5,6]. On the other hand, a study of patients with spinal metastases found that postoperative radiation was associated with increased risk of infection [7].

As no studies have been conducted addressing the tailoring of antibiotic prophylaxis in oncologic patients undergoing tumor surgery pre- or post-radiation or chemotherapy, including endoprosthetic reconstruction, prophylaxis should be given in accordance with existing guidelines for arthroplasty and other orthopaedic surgical procedures with foreign body placement [1,8]. In the event of colonization with methicillin-resistant *Staphylococcus aureus*, the choice of intravenous antimicrobial prophylactic agent should be adjusted accordingly.

Authors: Mitchell Schwaber, Yaakov Dickstein, Elizabeth Temkin

QUESTION 6: Does the type, dose, and duration of antibiotic prophylaxis differ for patients undergoing oncologic endoprosthetic reconstruction compared to conventional total joint arthroplasty (TJA)?

RECOMMENDATION: No. There is no recommendation to adjust type, dose or duration of antibiotic prophylaxis in patients undergoing oncologic endoprosthetic reconstruction from that which is routinely administered in conventional TJA.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 93%, Disagree: 0%, Abstain: 7% (Super Majority, Strong Consensus)

RATIONALE

Rates of infectious complications following knee and hip arthroplasty are generally less than 2% [1]. However, rates of infectious complications following lower-extremity limb salvage therapy with endoprostheses are approximately 10% [2]. The reason for this difference remains unclear, possibly due to systemic factors not directly related to the presence of localized malignancy [3].

Preoperative parenteral antibiotics have been demonstrated to reduce wound infections following TJA [4]. In a meta-analysis of antibiotic prophylaxis in TJA, which included 7 studies with 3,065 participants, the relative risk of infection was reduced by 81% compared to placebo [4]. None of the studies included in the meta-analysis or accompanying systematic review specifically addressed prophylaxis in patients undergoing orthopaedic endoprosthetic reconstruction.

Based on the preponderance of evidence, clinical guidelines recommend the use of perioperative parenteral antibiotics before TJA and other orthopaedic surgeries with foreign body placement [5,6]. No data exist regarding the tailoring of prophylaxis in oncologic patients with endoprosthetic reconstruction. Therefore, antibiotics should be given in accordance with accepted regimens.

1.2. PREVENTION: CHEMOTHERAPY

Authors: R. Lor Randall, Brian M. Smith, Karan Goswami, John S. Groundland, Antonios I. Papadopoulos, Panayiotis J. Papagelopoulos

QUESTION 1: Do we need to evaluate the gut and skin microbiome of patients after chemotherapy to assess the risk for potential infection after endoprosthetic reconstruction?

RECOMMENDATION: Unknown. There is no evidence in the literature to suggest that evaluation of the gut and/or skin microbiome following chemotherapy aids with risk stratification for potential infection in patients undergoing endoprosthetic limb salvage surgery.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

In the orthopaedic oncology literature, infection rates following metallic endoprosthesis limb salvage surgery are high and vary from 2.2–34% [1–4]. In a systematic review of the literature, Henderson et al. found the overall rate of infection-related failure of endoprostheses to be 7.8% and infection as the most common mode of failure in their current investigation of primary endoprostheses. Proximal tibia replacements and total femur replacements were noted to be at particular risk, requiring infection-related revision surgery in 19.7% and 17.5% of cases, respectively [1].

While not fully understood or rigorously investigated, the causes of these high rates of infection are likely multi-factorial, including extensive surgical dissection and resection, increased operation time, substantial loss of blood, inadequate soft tissue coverage, implantation of large constructs with foreign material and, often in the case of oncology patients, a poor nutritional and compromised immune status [5].

Perioperative chemotherapy has been shown to increase the total revision rates of endoprosthetic reconstruction to 40% from 10% due to its reduction of osseointegration [6]. The impact of chemotherapy on the rates of infection following endoprosthetic reconstruction remains unclear. There are conflicting reports on whether immunological deficiency following chemotherapy is a risk for postoperative infection of endoprostheses. In a review, Kapoor and Thiyam documented that a compromised immune status after neoadjuvant chemotherapy may result in postsurgical infection having an increased infection rate of 20% [5]. While in a multicenter retrospective review, Morii et al. showed chemotherapy did not affect infection risk and suggested no drawbacks related to chemotherapy in regards to postoperative infection control of endoprostheses [2]. It was shown that some patients who developed infection during postoperative chemotherapy were controlled by amelioration of myelosuppression alone, while others required revision and antibiotic therapy [7].

Any measure that leads to decreased infection rates of metallic endoprosthesis reconstruction would be desirable. Given the prevalence of the problem and the severity of the consequences of deep infection, even weak evidence supporting a decrease in postoperative infection rates would be worth considering. While a few interven-

tions have been noted to be beneficial, as reported in retrospective case series, no rigorous, prospective studies have been completed in this population. In regard to the question above, there is no evidence (level I, II, III or IV) to support or reject evaluation of the skin or gut microbiome after neoadjuvant or adjuvant chemotherapy.

Conceptually, chemotherapy is known to alter the gut microbiome, which likely influences the development and manifestations of chemotherapy-associated mucositis [8–10]. When undergoing induction chemotherapy for acute myeloid leukemia, patients who developed infection after treatment were shown to have significantly lower baseline stool bacteria diversity and the therapy itself was shown to decrease microbiome diversity [11]. Taxonomic shifts in the gut biome have been demonstrated in lymphoma patients following chemotherapy, with decreases in Firmicutes (species including *Staphylococcus, Streptococcus, Enterococcus*) and Actinobacteria (*Streptomyces, Proprionibacteria*) and increases in Proteobacteria (*Escherichia, Salmonella, Vibrio, Helicobacter, Yersinia, Legionellales*) [8]. In a pediatric study of acute lymphoblastic leukemia (ALL), the abundance of Proteobacteria in the gut microbiome before chemotherapy was predictive of the infection risk and domination of the gut by *Enterococcaceae* or *Streptococcaceae* during current and subsequent phases of chemotherapy [12]. Decreased diversity in the taxa of the gut microbiome has been used as a predictive tool for chemotherapy-related bloodstream infection risk [13]. Chemotherapy alters the skin microbiome in that fungal infections are common during and following chemotherapy [14].

Despite these documented changes in the microbiome of the gut and on the skin and their relation to infection risk, there is no proven association or theoretical link with postoperative endoprosthetic infection. This is illustrated in two ways. First, the causative organisms of endoprosthetic infection are those typically found in postoperative periprosthetic joint infections (e.g., *Staphylococcus, Streptrococcus, Enterococcus,* Pseudomonas species) [2,7,15], which are not species noted to increase following chemotherapy (e.g., *Proteobacteria* and Fungi) [8]. Second, the average time to infection-related surgical revision of endoprostheses is 47 months following index endoprosthesis placement [1]. This timeline is long after chemotherapy has been completed and more than enough time for chemotherapy-induced changes in the diversity of the gut and skin microbiome to return to normal.

There is still a need for further research to clarify whether skin and gut microbiome testing would prove useful in risk stratification for infection following endoprosthetic reconstruction.

QUESTION 2: Should an absolute neutrophil count of >1000/mm³ be the minimum for patients undergoing limb salvage surgery after receiving chemotherapy?

RECOMMENDATION: Yes. An absolute neutrophil count of >1000/mm³ should be the minimum for patients undergoing limb salvage surgery after receiving chemotherapy.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Neutropenia has been defined as an absolute neutrophil count (ANC) of 1500/mm³ or lower [1]. Historically, this cutoff value has been considered as a risk factor for developing infections and complications. Bodey et al. [2] initially described this association. They observed that the infection rate in patients with ANC below 1000/mm³ was 14% and below 100/mm³ up to 60% [2]. Furthermore, lower ANC levels have been identified as an independent risk factor for infections [3]. This latter publication also demonstrated that the

risk gradually increases as ANC decreases. In a more recent study, Lima et al. [4] evaluated patients with ANC levels less than or equal to 500 cells/mm³ further support this relationship.

Different chemotherapeutic agents are used in the treatment of bone and soft tissue sarcomas. Some have shown to be myelosuppressive and thus reduce the ANC [5]. This is also one of the most critical criteria to administering chemotherapeutic regimens as it has been directly associated with an increased risk of complications [3,6]. The combination of wide resection and neo-adjuvant/adjuvant chemotherapy is a standard treatment modality for bone sarcomas [7]. The combination of methotrexate (MTX), doxorubicin (ADR), cisplatin (CDDP) and ifosfamide (I) are agents used for conventional osteosarcoma [7–11]. For small round cell sarcoma including Ewing's sarcoma, multi-agent chemotherapy with vincristine-doxorubicin-cyclophosphamide, ifosfamide-etoposide (VDC-IE) is used [12,13]. Chemotherapy for high-grade non-round cell, soft tissue sarcoma is controversial, but the effectiveness of chemotherapy for such sarcomas has been shown in several studies [14–20]. The conventional key drugs for such condition include ADR and I [14,15,17]. In addition, dacarbazine (DTIC), gemcitabine (G) and docetaxel (D) became the options for soft tissue sarcomas [20–24]. Recent innovation in this area provided additional reagents including pazopanib, trabectedin and eribulin, which are mainly used as second line treatment for advanced soft tissue sarcomas [25–31].

When evaluating patients with low ANC undergoing surgical interventions, these patients also exhibit an increased risk of surgical site infection compared to patients with normal counts. Natour et al. [32] evaluated patients undergoing abdominal surgery in the setting of neutropenia. They categorized patients with ANC < 500/mm³, between 500/mm³ and 1000/mm³, and between 1000/mm³ and 1500/mm³. Patients with lower ANC also exhibited higher postoperative infection rates, hospital stay and mortality. A relatively recent study evaluated the risk for infection of implantable port devices in pediatric oncology patients [33]. Again, patients with low ANCs had higher infection rates compared to those with normal ANC.

No study was identified that directly associates infection risk in patients undergoing limb salvage and low ANC. Given that limb salvage surgery is a complex procedure, all efforts to avoid infection should be undertaken. Based on the available literature, we consider that patients with an ANC below 1000/mm³, either from the chemotherapy or the solid tumor itself, should not undergo limb salvage surgery until ANC is above 1000/mm³ and possibly above 1500/mm³.

QUESTION 3: Should the serum white blood cell (WBC) count be taken into account prior to endoprosthetic reconstruction in patients who have undergone recent chemotherapy?

RECOMMENDATION: The association between chemotherapy and infection following endoprosthetic reconstruction remains controversial. However, in a multifactorial decision making process, there may be some benefit in accounting for the serum WBC count prior to endoprosthetic reconstruction.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Infection continues to be one of the most serious complications after the reconstruction of an extremity using a tumor endoprosthesis. Past reports showed that the infection rate of a tumor endoprosthesis ranged from 4–36% [1–5]. The myelosuppressive properties of many chemotherapeutic drugs remain a theoretical risk for developing infection in these patients receiving a tumor endoprosthesis for an extremity tumor or metastatic lesions. However, this theoretical risk remains controversial. A handful of studies demonstrate a significant relationship between chemotherapy and periprosthetic infection in patients receiving an endoprosthetic device for an extremity tumor [3,6–9].

On the contrary, there are numerous studies that provide data supporting the idea that chemotherapy is not a significant risk factor for the development of periprosthetic joint infection (PJI) and surgical site infection (SSI) in these patients. Peel et al. [10] were able to demonstrate that chemotherapy, febrile neutropenia and bacteremia were not associated with the development of PJI. Jeys et al. [11] showed that there was no significant relationship between chemotherapy and the risk of infection. Biau et al. [12] reported that there was no significant difference in the rate of infection between patients who had received adjuvant treatment (including irradiation and chemotherapy) and those who had not received such treatment ($p = 0.13$). Finally, Meijer et al. [13] found no association between chemoradiation and increased rates of endoprosthetic infection.

Despite the conflicting evidence surrounding chemotherapy and the risk of endoprosthetic infection, there may be some benefit in taking into account the patient's serum WBC count prior to endoprosthetic reconstruction. It is widely known that lymphocytes play an essential role in combatting invading pathogens and facilitating wound healing after surgery [14]. In addition, Gulack et al. [15] reported that preoperative leukopenia prior to emergent abdominal surgery was a predictor for significant postoperative morbidity and mortality. However, they were not able to demonstrate a significant difference in the incidence of deep wound infection in patients with leukopenia vs. patients with a normal WBC count preoperatively ($p = 0.462$). These findings contrast with the work by Natour et al. [16], who noted that patients undergoing abdominal surgery with a preoperative absolute neutrophil count (ANC) less than 500 had significantly higher postoperative infection rates compared to patients who had a preoperative ANC between 500 and 1500. However, one must be cautious with the results from these studies, as they may not be generalizable to the particular patient cohort of focus.

Due to the fact that the literature doesn't show any significant differences between the infection rates between patients who are undergoing chemotherapy and those who are not receiving it, it makes sense to determine the WBC number as an additional diagnostic tool.

QUESTION 4: What should be the time delay between preoperative chemo/radiotherapy and a surgical tumor resection in order to minimize incidence of surgical site infection/ periprosthetic joint infection (SSI/PJI)?

RECOMMENDATION: Unknown. There is no data that supports the best time delay between preoperative chemo/radiotherapy and a surgical tumor resection to minimize the incidence of SSI/PJI. There are multiple intrinsic factors of each patient that can determine the best time to implant an endoprosthesis after a neoadjuvant treatment. Although no significance was seen between preoperative radiotherapy and surgical timing on wound complications (WC), trends suggest rates are lower if surgery is performed between 3 and 6 weeks following radiotherapy.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

SSIs, PJIS and WCs can occur postoperatively with respect to musculoskeletal/orthopaedic related surgeries. The risk of these infections is more common when these surgeries are related to musculoskeletal tumor resections following established multimodal therapies of preoperative chemotherapy and/or radiotherapy [1,2]. SSIs are defined as infections occurring at the operative site that develop within 30 days of non-implant operation or 1 year in the case of implant (artificial material) based operations [3]. The incidence of SSIs following orthopaedic operations is 1–3% [4]. The incidence is expected to be much higher following surgery in malignant musculoskeletal tumors due to many patients' requiring preoperative/postoperative chemotherapy and/or radiotherapy. PJI after joint replacement surgery has been reported to occur in 1.55–2.5% of cases [5–7]. As with SSIs the incidence would be expected to be higher following tumor surgery. Wound complications rates have been shown to be higher in those receiving preoperative radiotherapy [6,8–10].

With respect to the timing of surgery after preoperative radiotherapy and/or chemotherapy, there is no established optimal timeframe for clinical practice. Decisions to date are made by clinician-team opinion. The effect of different timeframes on the development of SSI, PJI and WC rates in this group has not been extensively reviewed. We know that radiation impairs wound tissue repair though several mechanisms [11]. Ionizing radiation can damage fibroblasts leading to slow growth [12,13], dermal atrophy, necrosis and ultimately reduced wound strength [14–16]. As a result, in the initial period following radiotherapy, surgery is avoided and four weeks is thought to be required to allow for repopulation of normal tissues [17]. Acute systemic effects of chemotherapy are also well documented, including toxicity and immunosuppression. However, there is still no established timeframe with respect to when to surgically resect tumors post chemotherapy and this is guided by clinical assessment and clinician choice.

All seven included studies were retrospective case studies, four were single-center studies, while the other three were not specified. The total sample number of all seven studies combined was n = 1,585; sample sizes ranged from 18-798. Preoperative radiotherapy was used in five of the studies, preoperative chemotherapy in three.

SSI was statistically significant secondary to preoperative radiotherapy alone in three studies [19,21,23] and secondary to preoperative chemotherapy in two studies [21,22]. No statistical significance with respect to SSI and preoperative chemotherapy in one study [18]. The remaining two studies did not statistically assess SSI as an outcome measure [17,20]. Sugita et al., 2015, intended to study the effect of timing between radiotherapy and surgery on SSI; however, this was abandoned due to factors varying widely between cases [19].

None of the six included studies assess PJI as an outcome measure. There was no mention of PJIs being included in any other groups as a complication. Furthermore, no data on the effect of timing between radiotherapy and surgery on PJI was sourced.

One study showed statistical significance between neoadjuvant radiotherapy and postoperative infection, p = 0.008. This study did not classify specifically the type or location of these infections [23].

In terms of WC two of the studies assessed their association with preoperative treatment. Both studies looked at the effect of preoperative radiotherapy. Keam et al. (n = 165) investigated the effect of preoperative radiotherapy on WCs and no statistical difference was evident with univariate analysis (p = 0.11) [20]. This study also looked at the timing effect of < 30 (n – not specified) days and ≥ 30 days (n – not specified) between radiotherapy and surgery on WC rates. There was no statistical significance between these two timeframes (p = 0.59) [20]. Griffin et al., investigated the dichotomous effect of the time intervals of 3, 4, 5 and 6 between preoperative radiotherapy and surgery. The rate of wound complications was the primary outcome measure. When comparing ≤ 3 and > 3 weeks, WC rates were 15/39 (38%) and 227/759 (30%) respectively, p = 0.3. Comparing ≤ 4 and > 4 weeks, WC rates were 39/129 (30%) and 203/669 (30%) respectively, p = 1. Comparing ≤ 5 and 5 weeks, WC rates were 88/295 (30%) and 154/503 (31%) respectively, p = 0.8. Comparing ≤ 6 and 6 weeks, WC rates were 133/479 (28%) and 109/322 (34%) respectively, p = 0.08. At time points < 3 and ≥ 6 weeks, it is evident that

Behnke et al., 2014 [23]	Non-specified Retrospective	Radiotherapy	Not specified	56	Postoperative infection (Location/type not specified) in those with radiotherapy 14/56 (25%) when compared to those without 37/340 (11%), statistically significant, $p = 0.008$

there is a higher rate of WC (34-38%) when compared to 3-6 weeks (28-31%); however, statistically there is no difference between time points [17]. This trend, although not significant, may support the general avoidance of aiming for surgery too early or too late based on radiation induced local changes to tissue and skin. A large multi-center study may show more of an effect at these timeframes. This trend may be considered applicable to SSI/PJIs due to WC risk factors being theoretically close in nature to infection risk, particularly the local and systemic toxicities and effects of radiotherapy and chemotherapy respectively.

We identified seven relevant articles assessing the effect of preoperative treatment on SSI, PJI and WC with respect to musculoskeletal tumour resection. Results are highly variable between the studies and overall there is limited evidence of significance in results. SSI rates were significantly increased in 3/3 (100%) of studies that looked at preoperative radiotherapy and 2/3 (67%) of the studies that looked at preoperative chemotherapy. These are single center/non-specified studies; to further delineate results, larger multi-centre studies in the future are warranted. No effect on timing of preoperative treatment and surgery was observed with respect to SSI rates. Given that there is conflicting evidence between the effect of preoperative tumour treatment and SSI development, investigation into the effect of timing becomes difficult. However, as some studies have established positive association and the near future possibility of larger multi-center study results coming to fruition, it will be now be imperative to also investigate and study the effects of surgical timing post radio/chemotherapy on rates of SSI. No studies assessed periprosthetic joint infection specifically as an outcome. This may be due to PJI presenting as a rare outcome secondary to surgical tumour resection. Also, these infections may be included in another complication section of such studies. None of the studies included in this review have mentioned this as an observed complication. Therefore, more investigation and study is needed with respect to understanding the role of preoperative tumour management and surgical timing on the rates PJI.

In summary, there is strong evidence supporting the association between preoperative radiotherapy/chemotherapy and postoperative SSIs. There is no data on the association of preoperative treatment with respect to PJI rates. One study showed no association between preoperative radiotherapy and WC. There were two studies showing no significant difference between surgical timing post radiotherapy/chemotherapy with respect to wound complications; however, there was a trend towards higher wound complications rates in ≤ 3 weeks and > 6 weeks. More large-scale, well-designed

multi-center studies are required to more accurately assess the effect of timing between preoperative radiotherapy/chemotherapy and surgery on the rate of postoperative SSIs, PJIs and WCs.

QUESTION 5: What strategies should be implemented to minimize the risk of surgical site infection/periprosthetic joint infection (SSI/PJI) in patients who have received chemotherapy or radiation therapy and are undergoing endoprosthetic reconstruction?

RECOMMENDATION: We believe patients who have received either chemotherapy or radiotherapy prior to endoprosthetic reconstruction should undergo extensive medical optimization. Consideration may also be given to the use of antimicrobial coated implants, extended (>24 h) and augmented postoperative antibiotic prophylaxis consisting of a first-generation cephalosporin and an aminoglycoside and/or vancomycin, as well as use of enhanced soft tissue reconstruction techniques. Surgery should also be expeditious in these patients minimizing dissection of soft tissues with gentle handling.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Patients with neoplasia undergoing endoprosthetic reconstruction are at an increased risk of SSI/PJI. The chemotherapy-induced immunosuppression, the poor soft-tissue conditions due to radiotherapy, the length and complexity of the tumor resection and megaprosthetic reconstruction and the difficulty of achieving soft tissue coverage are some of the reasons that explain the very high rate of infection in these patients compared to patients undergoing conventional arthroplasty [1–5].

As these patients are at high risk of SSI and/or PJI, any measure proven to be effective against infection should be implemented. Several organizations have proposed evidence-based guidelines for the prevention of surgical site infections. These strategies, together with additional measures, should be implemented in these patients. We provide examples of some of the measures that may be used to minimize the risk of SSI/PJI in patients undergoing oncologic endoprosthetic joint reconstruction, particularly in patients who have received chemotherapy and/or irradiation treatment. These measures include:

- Preoperative measures [6–9]: Correction of hyperglycemia, treatment of anemia, treatment of malnutrition, smoking cessation, decolonization of *Staphylococcus aureus* (including methicillin-resistant *S. aureus* (MRSA)), skin cleansing with chlorhexidine or other antiseptic agents prior to surgery and numerous other preoperative measures that are discussed elsewhere in the consensus document should be considered.

- Intraoperative measures [6–9]: Administration of weight-based antibiotics, including coverage against MRSA if present, re-dosing of the prophylactic antibiotic for cases that last longer than two hours or have increased blood loss, minimizing blood loss by administration of tranaxemic acid, minimizing operating room traffic, use of antibiotic-impregnated bone cement, wound irrigation with antiseptic agents such as sterile dilute betadine, careful and gentle soft tissue dissection and expeditious surgery are some of the proven strategies that may be implemented intraoperatively.
- Postoperative measures [6–9]: Wound management is a critical aspect of prevention of SSI/PJI in these patients. Consideration should be given to administration of less potent anticoagulation to minimize hematoma formation or reduce the chance for persistent wound drainage. The incision may be managed by application of negative pressure or occlusive dressing. Every effort should also be made to minimize blood loss and the need for allogeneic blood transfusion.

There are many other preventative measures that have been proposed or explored in oncologic patient population undergoing megaprosthetic reconstruction. In recent years the use of implants coated with antimicrobial agents such as silver and iodine has been explored. Silver-coated prostheses for limb reconstruction after tumor resection has been reported to have a favorable outcome and be effective in reduction of infection. Among the metals known to have antimicrobial activity, silver has attracted interest among many investigators due to its excellent level of antimicrobial activity and low toxicity. The silver coating can inhibit bacterial colonization of the prosthetic body and potentially prevent subsequent PJI [10–12]. A study involving patients with bone sarcoma over a five-year period demonstrated that the infection rate was substantially reduced from 17.6% in the uncoated titanium megaprosthesis (proximal femur, n = 33; proximal tibia, n = 41) to 5.9% in the silver-coated megaprosthesis group (proximal femur, n = 22; proximal tibia, n = 29). The titanium group data were retrospective and the data for the silver group were collected prospectively [13]. Another study evaluating the infection rate in 98 patients with sarcoma or giant-cell tumor in the proximal tibia demonstrated that infection at 16.7% in the group who underwent reconstruction using titanium megaprostheses (n = 42) was significantly higher than the infection rate at 8.9% in the silver-coated megaprostheses group, resulting in five-year prosthesis survival rates of 90% in the silver-coated and 84% in the titanium only cohort. Although not reaching statistical significance, further work may suggest that silver-coated tumor prostheses may reduce the PJI rate in the high-risk oncological patients submitted to tumor resection and limb reconstruction.

Another study retrospectively investigated 68 oncology patients, 30 of whom received a titanium proximal femoral replacement and 38 patients who received a silver-coated proximal femur replacement. There was a lower rate of early infections (within the first 6 months) in the silver-coated group (2.6%) in comparison with 10% in the titanium group. However, the difference was not statistically significant. Regarding late-onset infections (later than 6 months), the difference between groups was not clear (5.3% in the silver group and 6.6% in the titanium group) [14]. The reports available on the use of silver-impregnated implants are all retrospective with their inherent limitations. The role of silver coating of megaprostheses in prevention of infection needs to be explored in a prospective manner.

Currently, there are no appropriate guidelines or recommendations in place for prophylactic antibiotics in patients with neoplasm undergoing endoprosthetic reconstruction. Although the beneficial role of perioperative antibiotic prophylaxis is proven, it is not known whether continuation of antibiotics beyond the traditional 24 hours is beneficial. Further, there is no consensus among the experts on the type of antibiotic prophylaxis that may be needed in tumor surgery patients with great variation between centers. Although most surgeons provide gram-positive coverage, others also provide gram-negative coverage. In addition, the length of administration of postoperative antibiotics has varied vastly [2,15]. A cross-sectional international survey of practicing orthopaedic oncology surgeons found that 73% (95% confidence interval (CI) 61, 82%) of respondents prescribe a first-generation cephalosporin, 25% favor additional coverage with an aminoglycoside (gentamycin) and/or vancomycin or teicoplanin. Of those who prescribe a cephalosporin, 33% prescribe a dosage of one gram for all patients and the remainder prescribe up to 2 grams based on the body weight. One in three surgeons (95% CI: 25, 48%) believe antibiotics could be discontinued after 24 hours, but 40% of surgeons (95% CI: 30, 53%) continue antibiotics until the suction drain is removed.

In higher-risk cases of tumor patients who have received chemotherapy and/or irradiation, no guidelines exist to direct antibiotic management. It is a common practice to continue the antibiotics beyond 24 hours in these patients. There is no prospective study that has examined the efficacy of different antibiotic regimens in preventing infection in long-bone prosthetic reconstruction [15].

Studies comparing single-dose prophylaxis and multiple-dose prophylaxis in a general surgery setting have not shown any benefit to extended course of antibiotics [16]. A systematic review involving 48 studies on a total of 4,838 patients (level IV retrospective studies) suggests that long-term (greater than 24 hours) postoperative antibiotic prophylaxis is more effective at minimizing infection risk in patients with lower extremity long-bone tumors that require surgery and endoprosthetic reconstruction. However, the data should be interpreted with caution owing to the retrospective nature of the included studies. The overall pooled weighted infection rate for lower-extremity limb salvage surgery with endoprosthetic reconstruction was approximately 10% (95% CI: 8%–11%), with the most common causative organism reported to be gram-positive bacteria in the majority of cases. Twenty studies reported postoperative antibiotic regimens, so they were further subdivided into short-term regimens (0 to 24 hours of postoperative antibiotics) and long-term regimens (greater than 24 hours of postoperative antibiotics) and compared. The pooled infection rate following short-term postoperative antibiotic prophylaxis was 13% (95% CI: 9% to 17%; $p < 0.001$), which is slightly higher than the overall pooled infection rate. The pooled infection rate for the long-term postoperative antibiotic prophylaxis was 8% (95% CI: 6% to 12%; $p < 0.05$), which is slightly lower than the overall pooled infection rate. This difference in the pooled infection rates following short-term and long-term postoperative antibiotics was statistically significant ($p < 0.05$) [2].

There is no dispute to suggest that tumor patients undergoing endoprosthetic reconstruction are at higher risk of infection than those undergoing conventional joint arthroplasty. The risk of infection is further increased in patients who have received chemotherapy or irradiation treatment. Thus, any measure to minimize the risk of infection in this patient population needs to be implemented. We have proposed some preventative measures above but there is a desperate need for further studies to examine further measures.

* These authors answered a different question that was very similar to this one. The consensus voted to remove that question from publication due to its similarity with the current question. Though the question was removed, we want to acknowledge these authors for their work.

1.3. PREVENTION: RESEARCH CAVEATS

Authors: Rodolfo Capanna, Ivan Bohaček, Lorenzo Andreani

QUESTION 1: What are the significant risk factors for surgical site infection/periprosthetic joint infection (SSI/PJI) of an oncologic endoprosthesis following resection of a malignant bone tumor?

RECOMMENDATION: Patient-related risk factors for SSI/PJI of an oncologic endoprosthesis include increased patients' body mass index, overall presence of comorbidities, coexistence of superficial SSI or skin necrosis and lower preoperative hemoglobin or albumin levels. Disease-related risk factors for SSI/PJI of an oncologic endoprosthesis include lesion localization in proximal tibia, pelvis and lesion extending to pelvis from proximal femur. In addition, procedure related risk factors for SSI/PJI include preoperative hospitalization longer than 48 hours, resection of greater than 37% of the proximal tibia, resection of 3 or 4 heads of the quadriceps muscle in distal femoral lesions compared to 1 or 2 heads, increasing surgical time (longer than 2.5 h), use of cemented oncologic endoprosthesis, need for postoperative admission to the intensive care unit, increased postoperative blood transfusion requirement (2 or more units of allogeneic packed cells), presence of postoperative hematoma and the need for additional surgical procedures after the megaprosthesis implantation.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Periprosthetic joint infection represents one of the most challenging complications following any joint replacement and may result in devastating consequences. According to a recent systematic review, the mean rate of periprosthetic infection of a megaprosthesis (PMI) is 10% after primary procedure and 43% after revision procedures of infected cases [1,2].

Despite the lack of multiple randomized clinical trials, several retrospective studies (Level IV) showed significant risk factors for SSI/PJI of an oncologic endoprosthesis following resection of a malignant bone tumor. In a systematic review of the literature, De Gori et al. examined risk factors for PMI [3]. A total of 8 articles, all retrospective, including 2,136 patients, met the inclusion criteria and were analyzed [4–11]. The overall PMI rate was 14.2%. Patient-related factors associated with a significantly higher risk of PMI included increasing patients' body mass index and overall presence of comorbidities (but not the American Society of Anesthesiolgists (ASA) score or diabetes mellitus specifically) and coexistence of superficial surgical site infection or skin necrosis. Disease-related factors associated with increased risk for PMI included lesion localization in proximal tibia, pelvis and lesion extending to pelvis from proximal femur. In contrast, lesions localized in the distal femur appear to be protective for PMI occurrence. There was no association between primary tumor histological features or metastatic spread and PMI. In addition, there was no significant effect of chemotherapy and radiotherapy for the development of PMI, which is in contrast to several studies [12–15] which report increased incidence of infection rate associated with chemotherapy and radiotherapy. Controversy also still exists regarding whether primary or metastatic lesions have higher risk for PMI [3,12]. In this systematic review, procedure-related factors associated with higher risk of PMI included preoperative hospitalization longer than 48 hours, resection of greater than 37% of the proximal tibia, resection of 3 or 4 heads of the quadriceps muscle in distal femoral lesions compared to 1 or 2 heads, increasing surgical time (longer than 2.5 h), need for postoperative admission to the intensive care unit, increased postoperative blood transfusion requirement (2 or more units of allogenic packed cells), presence of postoperative hematoma and the need for additional surgical procedures after the megaprosthesis

implantation. According to this systematic review, features of perioperative antibiotic prophylaxis do not affect PJI rates, i.e., choice of antibiotic used, dosing, number of antibiotics used postoperatively or length of prophylaxis, which is in contrast to previous systematic review conclusions [1]. In addition, width of resection margins, bone resection length and extracapsular resection of knee tumors were not associated with increased rates of PMI. There was no difference in PMI rates according to prosthesis type or hinge movement, but two studies have shown that cemented megaprostheses have led to a higher PMI rate compared to uncemented ones, thus contradicting information regarding conventional arthroplasties. Routine use of gastrocnemius flap for anterior reconstruction and megaprosthesis coverage following proximal tibia resection has led to a reduced rate of PMI. Data of this systematic review supports the idea that soft tissue condition merely influences the PMI rate [16].

According to a most recent Level III retrospective cohort study on 150 patients, reported by Meijer et al., factors associated with infection after reconstructive shoulder surgery for proximal humerus tumors were lower preoperative hemoglobin or albumin levels and these patients should undergo optimization before surgery [17]. In addition, a lower WBC count and positive resection margins were associated with superficial infection and younger age with deep infection [17]. Furthermore, the location of the endoprosthesis may also influence the infection risk as the lower extremities have been demonstrated to have a greater risk of infection than the upper extremities [15].

QUESTION 2: What metrics should be used to determine the optimal timing of reimplantation for patients with a resected oncologic endoprosthesis?

RECOMMENDATION: Prior to reimplantation of an oncologic endoprosthesis after a previous resection, surgeons must ensure that the infection has been eradicated from the surgical bed. This would be determined via a sterile aspirate from the joint cavity following the antibiotic treatment.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Periprosthetic infection following oncologic endoprosthestic limb salvage surgery is a well-recognized and devastating complication [1]. Surgeons who treat oncologic patients with endoprostheses need to have a low tolerance to suspected periprosthetic infection. Oncology patients are at greater risk of infection than general arthroplasty patients, up to 15% of oncological endoprosthetic reconstructions compared to 1-2% within the general population [2,3]. Early diagnosis and treatment are key to outcome. Surgical treatment options include amputation, irrigation and debridement, excision arthroplasty, and one- and two-stage revision, along with targeted antibiotic therapy. Two-stage revision involves initial irrigation, debridement, removal of the endoprosthesis with implantation of a cement spacer and later reimplantation of the device. Despite the established acknowledgement that the two-stage revision is the gold standard for surgical treatment [4], there is a limited amount of information on the clinical parameters that should be used to optimize the reimplantation of an endoprosthesis following initial staged debridement and resection.

A search of the literature found nine retrospective studies, six retrospective cohort studies and three retrospective case studies

TABLE 1. Endoprosthetic infection two-stage revision study data

Study Name	Study Type	Total Number of Patients	Number of Patients Who Developed Infections	Infected Patients Who Underwent Two-stage Revision	Patients With Infections Controlled Successfully (%)
Jeys et al., 2005	Retrospective cohort study	1264	136	58	42 (72%)
Funovics et al., 2011	Retrospective cohort study	170	12	2	2 (100%)
Hardes et al., 2006	Retrospective case study	30	30	15	12 (80%)
Donati et al., 1998	Retrospective cohort study	35	20	19	14 (74%)
Rao et al., 2006	Retrospective cohort study	9	9	9	8 (89%)
Manoso et al., 2006	Retrospective case series	11	11	11	10 (91%)
Grimer et al., 2002	Retrospective case series	34	34	34	25 (74%)

[5–13]. Seven of these studies required clearance of residual infection as determined by a sterile aspirate sample from the periprosthetic space before the revision endoprosthesis could be reinserted [5–11]. These studies showed the success rate of preventing reinfection ranged between 72-100% if reimplantation was conducted using this metric.

The results of four studies following one-stage revision to control infection varied. This approach was performed when the operating surgeons deemed the infection was early in its course or low grade. Funovics et al. reported success rate of 62.5% (5 out of 8 patients) [6]. Jeys et al. found 47% (15 out of 32) of one-stage revisions eradicated the infection [5]. Hardes et al. only found success in 1 out 3 patients (33%) treated with this technique [11]. Holzer et al. reported a success rate comparable to those reported by two-stage revisions at 78% (14 out of 18 patients cleared their infections) [12]. The results of these studies show that the efficacy of one-stage revisions in treating infected oncological endoprotheses is inferior to that of a two-stage approach following negative aspirates. However, the low sample numbers make it difficult to draw a definitive conclusion.

Finally, four of the studies also reported on the importance of adequate soft tissue coverage prior to reimplantation [9–11,13]. This was used as a subjective clinical parameter. Three studies noted that the decision to proceed to the second stage was delayed until adequate soft tissue coverage and wound healing was seen [10,11,13]. Rao et al. noted the influence of different types of soft tissue flaps on infection control in two-stage revisions [9].

Despite the lack of higher quality literature, there has been consistent support by several retrospective studies for using sterile periprosthetic cavity aspirates as a clinical metric to indicate optimal timing for oncological endoprosthesis reimplantation. Other subjective parameters, such as soft tissue coverage and stage of infection, were also recorded. While clearer parameters exist in revision cases for general arthroplasty, more robust evidence, including larger sample sizes and randomized clinical trials, are desired for oncological endoprosthesis. Thus, only a moderate strength recommendation can be provided.

1.4. PREVENTION: SURGICAL TECHNIQUE

Authors: Aare Märtson, Oscar Ares, Jacek Markuszewski, Ignacio Moya, Andrea Sallent

QUESTION 1: Is there an increased risk for subsequent surgical site infection/periprosthetic joint infection (SSI/PJI) when a drainage tube is used in musculoskeletal tumor surgery?

RECOMMENDATION: Surgical drains should be used selectively in patients undergoing musculoskeletal tumor surgery. If used, they should be continuously monitored and removed immediately once output has decreased adequately per clinical judgment. There is a potential, yet unproven, link between the use of surgical drains and increased risk of SSI/PJI following orthopaedic procedures involving the use of prostheses.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Known risk factors for infection after musculoskeletal tumor surgery include malignancy of the primary tumor, duration of operative time, history of previous surgeries, use of chemotherapy and/or radiotherapy, tumor affectation of the skin and skin necrosis [1]. An additional area of concern in which more information is desired involves the use of surgical drains postoperatively in orthopaedic surgery patients undergoing oncologic procedures. Due to the extensive tissue dissection and exposure needed for musculoskeletal tumor removal, it is not uncommon for drains to be used postoperatively [2–6]. A consensus regarding the risk of SSI/PJI in musculoskeletal tumor surgery due to surgical drain use/duration of the drain remaining in situ has yet to be established.

The relationship between the use of surgical drains and the onset of infection has been examined in previous works. In a review of 723 musculoskeletal tumor surgeries among patients where drains were kept in 2-3 days (non-pelvic tumors) and 5 days (pelvic tumors), Rossi et al. found an overall infection rate was 8.7% [5]. Literature has a tendency to signal drainage tubes increase infection risks in musculoskeletal tumor surgeries. This may be due to the fact that they connect the endoprosthesis or the site affected by the tumor with the outside flora, thus making colonization by microorganisms, such as *Staphylococcus aureus*, more likely. Rates of SSI, with skin flora bacteria, such as *S. aureus*, have been increasing over the last decade. The exact reason for this increase is unknown but could relate to the use of surgical drainage in patients undergoing musculoskeletal tumor surgery [6].

To date, there is no consensus on how long surgical drains should remain in place after surgery and whether or not they contribute to the risk of orthopaedic oncology patients developing SSI/PJI. Per the World Health Organization (WHO), low-quality evidence shows the early removal of wound drains has neither benefit nor harm in reducing the SSI rate when compared to its late removal among any patient undergoing a surgical procedure [7]. Lerman et al. conducted a retrospective review of 165 patients with musculoskeletal tumor surgeries [3]. In their cohort, 10.3% of all patients had 2 surgical drains remain intact 24 hours postoperatively. However, surgical drain usage was not accounted for in the study's univariate analysis. In Shehadeh et al.'s retrospective review of 232 patients, overall infection rates in the group were similar at 11.36% [4]. In their protocol, drain tubes were removed when their debit was less than 30cc since the last shift. As with Lerman et al.'s study, commentary cannot be made regarding the influence drain usage had on the rate presented, because it was not accounted for in the study's statistical analysis.

Further insight can be obtained by a meta-review done by the WHO. Thirty-four systematic reviews investigating the effect of drains compared to no wound drainage in terms of the related infection risk in patients undergoing various surgical procedures were reviewed [7]. Review of the meta-analyses showed a tendency towards a beneficial effect of not using a wound drain with regard to a reduced risk of wound infections with no statistical significance. One of the few proven benefits of drains is a reduced need for a change of the dressing and increased comfort (observed among patients receiving total hip arthroplasty) [8,9]. Taking these factors into consideration and current status of the literature, decision making is to be made at the discretion of the clinician at this time. Further investigation into surgical drain use and its influence on SSI/PJI in musculoskeletal tumor surgery is warranted.

QUESTION 2: When should a surgical drain be removed to minimize the risk of subsequent surgical site infection/periprosthetic joint infection (SSI/PJI) in patients who have received endoprosthetic reconstruction (EPR) following resection of a musculoskeletal tumor?

RECOMMENDATION: Based on the available literature, we recommend drains be removed within 24 hours of surgery.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Drains are plastic tubes that are used to prevent the formation of surgical site serous pockets (seromas) and blood pockets (hematomas), both of which may act as a space for potential surgical site infection in addition to causing pain [1]. In orthopaedics, drains are commonly used to reduce collection of fluid around the joint and potentially reduce subsequent SSIs despite little evidence showing their benefit [2,3]. The utilization of closed suction drainage systems in primary arthroplasty has been debated for many years. Anecdotally, the benefits of a drain are thought to be prevention of hematoma formation and therefore improved wound healing and decreased infection rates [2]. The main disadvantage is the creation of a communication between the deep tissues and the surrounding environment, providing a conduit for bacterial contamination [2]. In fact, drains are known to be risk factor for SSIs [4]. Patel et al. have reported a relative risk increase in SSIs of 42% with each additional day of wound drainage [5]. Despite the scarcity of evidence supporting their benefit and known risks, orthopaedic surgeons continue to utilize drains in their procedures [6].

PJI rates after elective total joint replacement are reported between 1-2% [7,8]. However, the risk of PJI following EPR is even higher with rates ranging between 10-25% [9,10]. Because drains are a known risk factor for SSIs, their use in orthopaedic oncologic procedures is of particular concern. Oncology patients are at increased risk because many of them are immunocompromised. Secondly, this patient population often develops a large dead space after tumor resection necessitating placement of a surgical drain to prevent hematoma formation in the postoperative period.

A large meta-analysis of all randomized controlled trials of drain use in orthopaedic surgery was published by Parker et al. in 2004. They found no significant difference between wounds treated with and without drains with respect to the development of wound infection, wound hematoma or reoperations for wound complications [11]. However, the drained wounds did have a significantly greater need for blood transfusion [11]. These overall findings have been shown in numerous other studies of patients undergoing arthroplasty, general surgical and orthopaedic trauma procedures [12–14].

In 2007, a Cochrane Systematic Review was conducted to assess the utilization of drains in orthopaedic surgery. Thirty-six studies involving 5,464 patients with 5,697 surgical wounds were included [2]. Many orthopaedic procedures were utilized, although there was no specific mention of oncologic patients in the review. Pooling of results showed no statistically significant difference in the incidence of wound infection, hematoma, dehiscence or reoperation between those who had a drain and those who did not [2]. The incidence of SSI was 1.9% in patients who received a closed suction drain and 2.4% in those who did not [2]. Blood transfusions were required more frequently in those who received drains [2]. Previous literature has found an association between blood transfusion and infection in both the arthroplasty and orthopaedic oncology literature [15,16]. Despite the described findings of previous literature and the increased blood transfusions in the drain group, an independent relationship between drain placement and infection was not found in the Cochrane review [2].

In terms of the timing of drain removal, the literature remains inconclusive. In their prospective study of 214 uninfected orthopaedic operations, Sankar et al. found no significant correlation between wound infection and duration of drain retention [17]. Another prospective study examined total hip and knee arthroplasty patients who all received suction drains. Upon drain removal, the patients' drain-sites were swabbed and the drain tips were sent for culture [18]. This study demonstrated that the likelihood of bacterial colonization increased while wound drainage decreased over time; however, this does not necessarily translate to clinical development of SSI and their recommendation for removal at 24 hours must be cautiously considered [18].

Willett et al. attempted to further examine the timing of drain removal by removing drains at 24, 48 or 72 hours and culturing the aspirates taken from the drain tip; they found increasing rates of positive cultures in the groups where the drain was removed later. However, this difference was not statistically significant [19]. The authors of this study conclude that their data affirm the risk of retrograde influx of organisms along the drain track if the drain remains in place longer than 24 hours [19]. However, because their results were not statistically significant, they were incorrectly drawing this conclusion.

From the arthroplasty and surgical literature, there is no evidence of benefit to extending antibiotic duration until drains are removed; however, this has not specifically been evaluated in a musculoskeletal oncology patient population [20,21]. Due to the scarcity of quality literature in this area and the lack of evidence suggesting a relationship between utilization of drains and SSI, an evidence-based recommendation regarding the use of drains and the timing of their removal cannot be made for orthopaedic oncology patients.

QUESTION 3: Does the type of fixation (cemented vs. uncemented) of an oncologic endoprosthesis influence the incidence of subsequent surgical site infection/periprosthetic joint infection (SSI/PJI)?

RECOMMENDATION: There is conflicting evidence surrounding this topic. Multiple studies have demonstrated superiority with cemented fixation of an oncologic endoprosthesis while others have suggested superiority with uncemented fixation. Therefore, the choice of the method of fixation should be made on the basis of all clinical indications, other than the influence of fixation on subsequent SSI/PJI.

RATIONALE

Limb salvage surgery has become the treatment of choice for musculoskeletal cancers due to advances within the field of orthopaedic oncology. The use of an oncologic endoprosthesis has become the procedure of choice in limb salvage surgery. Though there are many benefits in utilizing an endoprosthesis, the development of subsequent infection is one of the most common and feared complications.

Multiple studies have been conducted to examine the risk of postoperative infection associated with the type of fixation (cemented vs. uncemented). Moreover, the approval and universal use of antibiotic-impregnated cement has altered the landscape as it relates to the risk and type of infection.

A systemic review of 40 studies examining distal femoral replacement (DFR) cases and proximal tibial replacement (PTR) cases showed mixed results. One hundred and nine (5.8%) of 1,894 cemented DFR cases became infected while 65 (9.0%) of 721 uncemented DFR cases became infected. This difference was found to be statistically significant [1]. For cemented DFR replacements, linear regression analysis showed that the risk of infection increased over time ($p < 0.001$), but the risk for infection in uncemented DFR implants did not increase over time. The same systemic review showed that 109 (15.2%) of 716 cemented PTR cases became infected while 56 (14.1%) of 396 uncemented PTR cases became infected; this difference was not found to be statistically significant. The incidence of infection in PTR cases did not increase over time, regardless of the fixation method [1].

Pala et al. [2] reported that 20 (9.1%) of 220 endoprostheses originally implanted in patients with either a lower extremity primary bone tumor or metastatic disease became infected. Of these 20 cases, 12 (10.3%) were cemented and eight (7.7%) were uncemented. In addition, survival of cemented endoprostheses to infection was 68% at 60 months, while survival of the uncemented endoprostheses was 82% at 60 months [2]. Finally, in both univariate and multivariate analyses, the only variable that was found to be a predictor of survival was uncemented fixation [2].

The infection rates of endoprostheses vary widely in the literature. Studies investigating the infection rate after cemented fixation of an endoprosthetic device yielded an infection rate ranging from 5.2% to 21.9% [3–7]; studies investigating the infection rate after uncemented fixation yielded rates ranging from 9.7% to 12% [8–10]. A condition of equipoise exists resulting from the conflicting data supporting cemented or uncemented fixation and the incidence of subsequent SSI/PJI.

QUESTION 4: Does the use of incise draping with antibacterial agents (iodine) influence the risk for subsequent surgical site infection/periprosthetic joint infection (SSI/PJI) in patients undergoing musculoskeletal tumor surgeries?

RECOMMENDATION: There is some evidence claiming that antimicrobial-impregnated incise drapes result in a reduction in bacterial contamination at the surgical site. However, there is little evidence to demonstrate that it results in a subsequent reduction in the incidence of SSI and/or PJI.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Surgical incise drapes are often used by surgeons to reduce bacterial recolonization of the surgical site with host flora that may potentially predispose the patient to subsequent infection. Furthermore, it is important to differentiate antimicrobial-impregnated drapes from non-impregnated drapes as the addition of an antimicrobial agent, such as iodophor, may have a different effect on the rate of recolonization. The rationale behind the antimicrobial drape is that the incise drape can act as a physical barrier to block bacterial proliferation on the skin and potential entry into the surgical wound.

Multiple studies have demonstrated that incise drapes can result in a reduction in bacterial recolonization. In a prospective randomized controlled trial of 101 hips undergoing hip preservation surgery, Rezapoor et al. found that iodine-impregnated drapes resulted in a significant reduction (12.0% vs. 27.4%) in bacterial colonization compared to those without drapes [1]. Furthermore, Milandt et al. reported that the use of iodine-containing incision drapes did not increase bacterial recolonization in simulated total knee arthroplasty [2]. Dewan et al. reported that the use of an iodophor-impregnated plastic incise drape in abdominal surgery reduced the contamination of the wound [3]. Casey et al. evaluated the antimicrobial efficacy of an iodine-impregnated incise drape against methicillin-resistant *S. aureus* (MRSA) in a skin model and concluded that it had detectable antimicrobial activity [4].

While there is evidence to suggest that impregnated incise drapes result in a reduction of bacterial colonization, there is conflicting evidence demonstrating that impregnated incise drapes result in a significant decrease in the infection rate. Ritter et al. demonstrated a considerably low rate of SSI incidence (0.46%) in total arthroplasties performed with an antimicrobial incise drape [5]. In addition, Yoshimura et al. found that the lack of an iodophor-impregnated drape was a significant risk factor for wound infection after liver resection [6]. In contrast, a randomized study by Dewan et al. suggested that iodine-impregnated drapes did not result in a significant reduction in SSI rate in abdominal and cardiac surgery [3]. Furthermore, a randomized study by Segal and Anderson showed only a tendential reduction in the rate of SSIs by iodophor-impregnated adhesive drapes in high risk cardiac surgery [7]. Additionally, no SSIs were observed in a retrospective review of 581 patients undergoing anterior cervical fusions without iodophor-impregnated incision drapes. It was concluded that the use of iodophor-impregnated incision drapes during anterior cervical fusion was not needed [8].

In a Cochrane review of 3,082 patients, Webster et al. found that a higher proportion of patients developed surgical site infection with plastic drapes than patients in whom no drapes were used ($p = 0.03$) [9]. However, no difference was found when iodophor-impregnated drapes were used (rate ratio (RR) 1.03, 95% confidence interval (CI) 0.06 to 1.66, $p = 0.89$), which further highlights the importance of discriminating between antimicrobial and regular plastic incise drapes. In the World Health Organization guideline [10], four of the above-mentioned studies (one randomized-controlled trial (RCT) [7], one quasi-RCT [11] and two observational studies [6,12]) were identified that assessed the effect of using single-use adhesive incise drapes to reduce SSI. They commented that the two RCTs showed the use of antimicrobial-impregnated incise drapes may have some adverse effect, but the effect estimate was not statistically different from the control group. Furthermore, they noted that the observational studies reported that there may be a benefit in using antimicrobial-impregnated incise drapes, but the effect was not statistically different from the control group. They concluded that the quality of evidence for these comparisons was very low for both the randomized control trials and the observational studies due to the risk of bias and imprecision or inconsistency.

There is an extensive number of publications demonstrating that the use of antimicrobial-impregnated incise draping leads to a lower incidence of surgical site contamination. Studies demonstrating the beneficial effect of incise draping in reduction of surgical site infection, especially after tumor surgery, are lacking.

QUESTION 5: Does the use of soft tissue attachment meshes increase the risk for subsequent periprosthetic joint infection (PJI) in patients undergoing oncologic endoprosthetic reconstruction?

RECOMMENDATION: The current literature indicates that there is no increased risk of PJI in this patient population with the use of soft tissue attachment meshes. However, there are few studies directly comparing the use of mesh vs. not using mesh in comparable tumors/surgical locations, so further comprehensive study on the topic is necessary to say with reasonable certainty that there is no connection.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

The reported infection incidence after tumor resection and replacement with an endoprosthesis varies widely in the literature, ranging from 7.8% to 25% [1–3]. Tumor type and surgical site have a significant influence on the infection incidence [3,4]. Despite the variation reported in the literature, the infection burden for these procedures is much greater than that of primary joint replacement surgery for which the infection rate of hips and knees is estimated at 1% [5].

Infection in endoprosthetic reconstruction cases has been attributed to multiple sources, one of which is the use of surgical mesh. Surgical mesh has been suggested to act as a vehicle for infection. This risk is increased when the mesh is used alongside a large implant or neoadjuvant chemotherapy. Henderson et al. investigated complication incidence in a series of 534 endoprosthetic failures and found that infection was the most common mode of failure [4]. Cho et al. examined risk factors related to infection in a cohort of 62 patients who underwent proximal tibial endoprosthetic reconstruction. Prostheses were removed due to infection in 25.8% of the patients; however, application of synthetic mesh to stabilize the patella was not found to be a significant risk factor, nor was chemotherapy [1]. A 2017 study investigated patient outcomes using BARD® mesh for endoprosthetic reconstruction and reported that only one case of deep infection and two cases of superficial infection developed out of 51 patients [6]. A systematic review of reconstruction techniques after resection of proximal humeral tumors found that megaprosthesis with mesh had an infection rate of 4%, which was between the rates of hemiarthroplasty (0%) and reverse shoulder arthroplasty (9%) [7].

Polyethylenterephtalate mesh, known as a Trevira® tube, is a mesh option used for endoprosthetic reconstruction. A 2001 study of 69 megaprostheses implants with Trevira tube for soft tissue reconstruction reported that there was no significant increase in the rate of infection compared to implantation without a Trevira tube [8]. Similarly, Maccauro et al. examined a cohort of 36 patients with solitary bone metastases who underwent resection and endoprosthetic reconstruction, of which 20 of the patients received a Trevira tube. They also detected no significant difference in infection rate between patients who did and did not receive a Trevira tube [9]. Additionally, Schmolders et al. determined that replacement of the proximal humerus using a Trevira tube in combination with a modular endoprosthesis is a safe and viable treatment option for both bone tumors and metastases. They observed no statistically significant increased risk of infection by using a Trevira tube, even among immunosuppressed patients [10].

Surgical meshes for reconstruction of abdominal wall hernias and groin region hernias have been successfully used since the 1940s [11]. While abdominal hernia repairs do not incur the additional

infection risks of endoprosthesis implantation and immunosuppressive effects of neoadjuvant therapy, patient outcomes using synthetic mesh for abdominal hernia repair have been well studied and provide some insight regarding infection rates associated with the use of mesh. A recent meta-analysis of 10 randomized controlled trials comparing abdominal hernia surgery outcomes using mesh vs. surgical suture detected no significant difference in infection rates between the 2 groups. However, the mesh group did demonstrate significantly lower incidence of recurrent hernia than the surgical suture group, leading the authors to conclude synthetic mesh was a highly efficacious repair technique [12].

In summary, the published literature suggested little or no association between the use of mesh for soft tissue attachment with endoprosthetic reimplantation and development of subsequent PJI. Further study is needed before it can be conclusively determined that the use of soft tissue attachment meshes does not increase the risk for subsequent infection in patients undergoing oncologic endoprosthetic reconstruction. Future investigation should utilize larger cohorts and control for tumor type and location so that the use of mesh can be better isolated as the variable of interest.

QUESTION 6: Should endosprosthesis and/or allograft bone be soaked in antibiotic solution or antiseptic solutions prior to implantation in patients?

RESPONSE: Unknown. There is no evidence to suggest that the use of a pre-implantation antibiotic or antiseptic soak of an endoprosthesis or massive allograft would reduce the rate of surgical site infection/periprosthetic joint infection (SSI/PJI).

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

In the oncologic literature, infection rates following metallic endoprostheses and bulk allograft surgery are high. In a systematic review, Henderson et al. found the rate of infection-related failure of endoprostheses to be 7.4%, when all anatomic locations were taken into account. Proximal tibia replacements and total femur replacements were noted to be at particular risk for infection, requiring revision surgery in 19.7% and 17.5% of cases, respectively [1]. In a systematic review of pediatric oncology patients, Groundland et al. found an infection rate of 12.9% and 17.1% when bulk osteoarticular allografts were used to reconstruct the distal femur and proximal tibia, respectively [2].

While not fully understood or rigorously investigated, the causes of these high rates of infection are likely multi-factorial, including extensive surgical dissections and resections, substantial blood loss, implantation of large constructs with foreign material and, in the case of oncology patients, a potentially immunosuppressed host.

Any measure that leads to decreased infection rates of metallic endoprosthesis and massive allograft reconstruction would be desirable. Given the prevalence of the problem and the severity of the consequences of deep infection, even weak evidence supporting a decrease in infection rates would be worth considering. While a few interventions have been noted to be beneficial, as reported in retrospective case series, no rigorous, prospective studies have been completed in this population [3–8]. Regarding the question above, there is no evidence to support or reject the use of a pre-implantation antiseptic soak of the endoprosthesis (or allograft). Local application of an antibiotic solution (e.g., gentamicin) around prosthesis before closing the incision in conjunction with a parenteral agent as antibiotic prophylaxis is routine practice in some institutions [9]. However, antibiotic solutions have been found to offer no advantage over saline in the removal of bacteria from bone, titanium or stainless steel. In addition, there

are no efficacy data to support the use of antibiotic soaks in procedures with sterile prosthesis insertion [10,11]. There are no high quality trials testing the effectiveness of antiseptic soaking of prosthesis before implantation [12]. Moreover, antiseptics could exert changes in materials used for total arthroplasty (e.g., titanium alloy or hydroxyapatite), cause chondrolysis or pose cytotoxicity to human fibroblasts and osteoblasts [13,14].

Conceptually, a pre-implantation soak would decrease the bacterial load on the implant immediately prior to implantation, thereby reducing the risk of an infection caused by direct seeding of the wound bed by the implant itself. In an in vitro study bone fragments soaked with a solution of gentamicin or vancomycin for 30 minutes were loaded with an antibiotic concentration, 5-fold the minimum inhibitory concentration (MIC) values would be needed to provoke bacterial regression [15]. It has been also shown that in vitro decontamination of bone allografts contaminated with coagulase-negative Staphylococci is feasible after soaking bone with gentamicin or rifampicin for 60 minutes [16]. However, clinical studies are lacking, and there are no randomized controlled trials or systematic reviews that have evaluated soaking endoprosthesis or allograft bone in antibiotic or antiseptic solutions before implantation for the prevention of surgical site infections [17]. Two facts belie this practice. First, there is no published evidence that sterilized implants (endoprosthesis or allograft) routinely become colonized or contaminated from their unpackaging to implantation. Second, most infections in endoprosthesis and massive allograft surgery do not manifest in the perioperative period; rather, the average time to failure due to infection occurs years after the index surgery. In their report of 2,174 endoprosthesis surgeries, Henderson et al. reported an overall time revision surgery due to infection of 47 months, with a non-normally distributed standard deviation of 69 months [1]. The anatomic location with the fastest time to infection-driven revision was the elbow, occurring at a mean of 16 months, while the proximal humerus had an infection time of 80 months. A pre-implant soak would have no theoretical impact on these late infections.

QUESTION 7: Should a coated prosthesis (silver/iodine) be used for reconstruction of patients undergoing primary bone tumor resection?

RECOMMENDATION: Yes, silver coating and iodine coating of prosthesis show good results in prevention of infection after reconstruction following primary tumor resection.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Megaprosthesis has been used to reconstruct limbs and large skeletal defects after resection of bone tumors for many decades. A significant problem is the higher rate of infection as compared to an infection rate of < 1% after a standard primary arthroplasty procedure. Many factors have been cited in literature which include length of surgery, OR environment, blood transfusions, soft tissue available for coverage and segment involved, e.g., tibia vs. femur. The average infection rate reported in literature is 10% (range 0–25%).

TABLE 1. Major findings and conclusions in the literature on silver-coated megaendoprostheses*

Author, Reference	Journal, Year	Study Design	Patients (*n*)	Results	Conclusion
Gosheger et al. [16] Silver-coated megaendoprostheses in a rabbit model: analysis of infection rate and toxicological side effects	Biomaterials 2004	Animal trial	30 (silver n = 15, titanium n = 15)	The silver group showed significantly ($p < 0.05$) lower infection rates (7% vs. 47%) in comparison with the titanium group after artificial contamination with S. aureaus	The new silver-coated MUTARS megaprosthesis resulted in reduced infection rates in an animal trial
Hardes et al. [27] Lack of toxicological side effects in silver-coated megaprostheses in humans	Biomaterials 2007	Prospective	20	No sign of toxic side effect after implantation of silver-coated megaprostheses. The silver levels in blood were considered non-toxic. No changes in liver or kidney function	Silver coatings on megaprostheses show no local or systemic side effects
Hardes et al. [9] Reduction of periprosthetic infection with silver-coated megaprostheses in patients with bone sarcoma	Journal of Surgical Oncology 2010	Prospective (silver group); retrospective (titanium group)	125 (silver n = 51, titanium n = 74)	The infection rate was substantially, but not significantly, reduced from 17.6% in the titanium group to 5.9% in the silver group. Included were patients with a proximal femur or proximal tibia replacement	Using silver-coated prostheses reduced the infection rate over the medium term
Glehr et al. [28] Argyria following the use of silver-coated megaprostheses: no association between development of local argyria and elevated silver levels	Bone and Joint Journal 2013	Retrospective	32	Asymptomatic local argyria in 23% of patients with silver-coated megaprostheses. No systemtic toxicity due to silver	However, the majority of the patients received silver-coated prostheses in revision, so that due to a negative pH value, increased release of Ag+ ions may be suspected
Wafa et al. [31] Retrospective evaluation of the incidence of early periprosthetic infection with silver-treated endoprostheses in high-risk patients: case-control study	Bone and Joint Journal 2015	Retrospective	170 (silver n = 85, titanium n = 85)	This retrospective study showed a postoperative infection rate of 11.8% in the group with silver-coated prostheses vs. 22.4% in the group with uncoated prostheses ($p = 0.033$)	Silver-coated implants showed a reduced reinfection rate after PJI in two-stage revisions (success rates of 85% in sliver group compared to 57.1% in uncoated group, $p = 0.05$)
Politano et al. [20] Use of silver prevention and treatment of infections: silver review	Surgical Infections 2013	Review	--	Benefits of silver-coated orthopaedic prostheses are still unproved	
Wilding et al. [32] Can a silver-coated arthrodesis implant provide a viable alternative to above-knee amputation in the unsalvageable, infected total knee arthroplasty?	Journal of Arthroplasty 2016	Retrospective	8	With a mean follow-up period of 16 months (5-35 months), only one patient had recurrent infection, but prosthesis-preserving treatment was possible	The silver-coated arthrodesis is a good alternative to amputation, particularly in infected knee prostheses

*Adapted from Schmidt-Braekling T, Streitbuerger A, Gosheger G, Boettner F, Nottrott M, Ahrens H, et al. Silver-coated megaprotheses: review of the literature. Eur J Orthop Surg Traumatol. 2017;27(4):483–489.

Silver coating of prosthesis is one of the methods studied so far. A number of retrospective studies have reported a decrease in the infection rate following use of silver-coated endoprosthesis. However, evidence from prospective and randomized trials is lacking [1]. See Table 1.

The Kanazawa group developed an iodine coating and published their results for the first time in 2012. In their study, 222 patients received iodine-coated implants of which 64 had active infection [2]. Their results suggest an even greater efficacy in prevention of infection as compared to silver coating interval and even eradication of infection in cases with active infection. Subsequent reporting by the same group in 2014 has also shown greater efficacy of iodine-treated implants in patients with trauma, bone loss due to infections and tumor resection as well as revision setting with previously infected implants [3].

QUESTION 8: What is the most optimal local antimicrobial delivery strategy during limb salvage: antibiotic cement, silver-coated implant, iodine-coated implant, topical vancomycin powder, injection of antibiotics via drain tubing or other?

RECOMMENDATION: Unknown. No direct comparison has been made of different antimicrobial delivery strategies in oncological patients undergoing limb salvage procedures.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Surgical excision of primary malignant tumors and metastases of the bone frequently leads to large skeletal defects. While once amputation was typically the only solution, the introduction of megaprostheses and later modular megaprostheses has led to limb salvage becoming the standard of care [1]. Despite falling rates of mechanical failure, the risk of periprosthetic infection remains high in comparison with conventional arthroplasty [2]. Treatment of periprosthetic infections often requires surgical intervention and prolonged antibiotic therapy [3]. Ongoing efforts directed at finding an effective means of infection prophylaxis have been examined exclusively in small observational studies without direct comparison between methods, thus limiting their conclusions.

Published studies appear to support the use of silver-coated implants. Data exist for limb salvage in sites including the hip, proximal and distal femur, pelvis, proximal and distal tibia, humerus and radius [4–10]. Six cohort studies, all but one retrospective, compared oncological patients who received silver-coated implants with non-coated (mostly titanium) implants [4–8,10]. The results across the studies were uniform with fewer patients who received silver-coated implants developing periprosthetic infections than the patients who received non-coated prostheses.

Weak evidence from a single retrospective cohort study indicates that alloy-type megaprosthesis may influence the risk of subsequent infection [11]. Significantly more patients who received a cobalt-chrome prosthesis developed infection than patients who received titanium prostheses.

Very weak evidence exists suggesting that iodine-coated megaprostheses may reduce risk of periprosthetic infection [12]. Similarly, there are limited data supporting the use of iodine-coated hardware in patients undergoing reconstruction [13].

Despite the body of evidence on antibiotic-impregnated cement in arthroplasty, only one case series examined its effects specifically in orthopaedic oncology patients who underwent total knee prostheses [14].

Treatment

2.1. TREATMENT: IRRIGATION AND DEBRIDEMENT

Authors: Oscar Ares, John Abraham, John Strony, Keenan Sobol, Ignacio Moya, Andrea Sallent

QUESTION 1: How many irrigation and debridements (I&Ds) of an infected oncologic endoprosthesis are reasonable before consideration should be given to resection arthroplasty?

RECOMMENDATION: Decision to repeat irrigation and debridement and retention of an infected endoprosthesis (DAIR) should be made based on comorbidities of the host, virulence of the organism, complexity of the reconstruction and status of the soft tissues. We believe DAIR performed more than two or three times is unlikely to be successful.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

The utilization of musculoskeletal tumor surgery has increased through the years thanks to the increase in therapeutic alternatives. One of these alternatives is resection of the tumor and implantation of a tumor endoprosthesis. These surgeries are complex, long and aggressive for the surrounding tissues. There are many possible complications following these procedures, of which periprosthetic joint infection is one of the most feared.

Infection rates in primary musculoskeletal surgeries have been reported from over 5% to over 15% [1,2]. Several risk factors have been identified, including malignancy of the primary tumor, surgical time, previous surgery, the use of chemotherapy and/or radiotherapy, tumor affectation of the skin and skin necrosis [3]. Identification of these factors is crucial because the onset of infection increases the rate of morbidity, mortality, the number of subsequent procedures and amputation [4].

The optimal treatment for oncologic endoprosthesis infection is currently a matter of debate. Several authors have investigated the role of DAIR, including the number of attempts that should be made before undergoing more aggressive surgery.

Dhanoa et al. [5] reviewed 105 patients with oncologic endoprosthesis infections. In their experience, I&D could be performed when the case met the following criteria: acute onset infection (14–28 days), clear-cut diagnosis based on histopathology and microbiology, stable implant and susceptibility of the microorganism to an effective orally-available antimicrobial agent. With this method they reported a 42.8% rate of infection eradication. In those patients in which debridement failed, a two-stage revision surgery would be performed without trying a second debridement. A similar therapeutic strategy was demonstrated by Kapoor et al. [6]. Patients would undergo as much as one surgical debridement before switching to two-stage revision if the debridement had failed. Both authors agree that late prosthetic infections are associated with poor results when treated by lavage, debridement or prolonged antibiotics administration. Therefore, removal of the infected prosthesis either as one- or two-stage procedure, resection arthroplasty or an amputation becomes necessary. Funovics et al. [2] reported a 50% eradication rate after surgical debridement. In their experience, when debridement alone failed, one-stage revision surgery was performed.

Not all authors view debridement as an inferior method in treating endoprosthetic infection, however. Allison et al. [7] treated 329 musculoskeletal tumors and reported a 13.9% overall infection. Although they did not clarify how patients were selected for each treatment method, they reported a 70% healing rate after single-stage irrigation and debridement with exchange of the modular component and varying degrees of suppressive antibiotics. That healing rate was superior to the one they achieved after revision, antibiotic spacer placement and subsequent reimplantation (62%). On the other hand, Jeys et al. [8] claim that I&D alone has a poor outcome in endoprosthetic infection. After treating 136 patients, they reported only a 6% eradication rate after debridement only. They also state that healing after resection arthroplasty was achieved in 50% of cases, but they do not specify the reason why patients were treated one way or another.

Not all authors believe that surgical debridement should be a step in management of oncologic endoprosthesis infection. Holtzer et al. [9] treated 18 patients with endoprosthetic infection. They considered debridement a poor option and thus performed one-stage revision surgeries in all cases. Infection was eliminated in 14/18 patients (77.78%). In a similar manner, Hardes et al. [10] treated 30 patients and developed a therapeutic algorithm for oncologic endoprosthesis infection that did not include I&D. They believed that one-stage revision surgery should be performed whenever possible. If one-stage revision is not possible, then two-stage revision should be performed. If two-stage revision is not possible, then arthrodesis should be performed. Finally, if arthrodesis is not possible, then amputation should be performed. Out of 30 patients, 19 (63.33%) were cured with a one- or two-stage revision. Of the remaining 11, amputation was performed in 6/30 (20%).

In conclusion, it is unclear if I&D serves as a good alternative for the treatment of an infected endoprosthesis. In addition, the number of attempts that should be made towards I&D before revision surgery or amputation is uncertain. It seems that for acute infections with an antibiotic–sensitive microorganism, debridement

may be a good first step in the treatment algorithm, but failure rates are high, and no more than two surgical debridements should be attempted before considering a revision surgery in order to achieve infection eradication.

QUESTION 2: How should acute reinfection of an oncologic endoprosthesis be treated?

RECOMMENDATION: Acute reinfections in patients with oncologic endoprostheses demand treatment by surgical methods because the long-term administration of antibiotics alone is not sufficient. The most appropriate treatment modality for acute re-infection is debridement, antibiotics and implant retention (DAIR) with exchange of components.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Oncology patients represent a high-risk subset of the population. The implantation of endoprostheses in this cohort of patients leads to an increased risk of infection due to their immunocompromised state, previous radiotherapy, poor soft tissues, poor nutritional status or significant comorbidities [1].

Many options have been proposed to prevent infections of an endoprostheis. However, there are no current appropriate guidelines or recommendations to guide optimal management of an acute endoprosthetic reinfection. There is a paucity of literature regarding the results of these different procedures, though it has been shown that irrigation, debridement and prolonged antibiotic administration have the poorest results in treating late prosthetic infections [2]. Therefore, removal of the infected prosthesis either as one- or two-stage procedure or an amputation may be necessary [2].

Allison et al. reviewed 329 patients who had undergone arthroplasty surgery for definitive oncological treatment [3]. Of those that became infected and were treated with irrigation and debridement without component exchange, there was a 42% success rate at eradicating infection. With single stage exchange, this increased to 70%. Two-stage revision led to a 62% success rate. Conversely, previous literature has associated two-stage revisions as having a higher success rate when compared with one-stage [4–6]. As one would expect, amputation has been shown to carry the highest rate of infection eradication. The risk of amputation due to an infected endoprosthesis has been reported to be between 23.5% and 87% [4,7,8].

Periprosthetic infection can lead to a poor functional outcome as well as an increased morbidity and mortality. Management of infections after reconstructive surgery for bone tumors is a challenge, requiring careful planning, consideration of the patient's prognosis and a potentially aggressive surgical approach.

QUESTION 3: Is irrigation and debridement and exchange of modular parts a viable option for treatment of acute periprosthetic joint infection (PJI) involving oncologic endoprosthesis? If so, what are the indications?

RECOMMENDATION: Yes. Irrigation and debridement with retention of prosthesis (DAIR) is a viable option for management of patients with infected endoprosthesis. The procedure may be offered to patients with superficial early infection (< 3 months), short duration of symptoms (< 3 weeks), well-fixed implants and well-characterized organism demonstrating a highly susceptible pathogen.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Surgical reconstruction using an endoprosthesis after tumor resection is frequently associated with deep surgical site infection that leads to PJI. The prevalence of PJI associated with oncologic endoprosthesis is 7-28% compared to only 1-2% in primary joint replacements. Cancer patients are at a higher risk for developing PJI after receiving an endoprosthesis due to numerous risk factors, which lead to local and systemic immunodeficiency. These risk factors include chemotherapy, radiotherapy, prolonged surgical time, increased bleeding, larger implant surface area and compromised soft tissue envelope.

In case of an infected oncologic endoprosthesis, debridement, antibiotics and implant retention (DAIR) can be performed, especially in early acute infections (< 3 months). If DAIR fails to eradicate the infection, a two-stage revision is necessary. In the literature, two-stage revision is generally reported as a good surgical approach for infection control with a reported success rate of 63-100% [1–6]. Eradication of infection is generally worse after a single-stage revision and, of course, better after an amputation [4,7–9].

In order to optimize the treatment of patients with an infected oncologic endoprosthesis we performed a literature search to assess factors associated with successful eradication of the infection after DAIR. Although various studies assessed infection of oncologic endoprostheses, only few specifically evaluated the efficacy of DAIR [2,3]. We assessed the literature for indications as well as factors that influenced the treatment outcomes of DAIR. Due to the lack

Chambers 1962 [18]	Narrative review	X	X	X	* Article on the bactericidal effects of silver (1f).
Dhanoa 2015 [1]	Retrospective cohort 2007–2011	N = 105 Endoprosthetic reconstruction for tumor	* 54% DAIR * 46% 2-SR	32 months	* 12.4% infection at 0-63 months. * Higher risk after additional procedures (13x), comorbidity, proximal tibia endoprostheses, pelvic endoprostheses and preoperative hospitalization >48 hour. Lower risk with distal femoral prostheses. * 80% of infections had operations >2.5h, compared to 16.3% in non-infections. * 38% Staph aureus, 31% CNS, 23% Klebsiella pneumoniae, 23% Pseudomonas aeruginosa. 38.5% had polymicrobial infection (1d). * 80% of 2-SR were successful; 1 patient had antibiotic suppression. * 43% of DAIR were successful; 2 patients had antibiotics; 2 patients had amputation (2).
Donati 2016 [19]	Retrospective case-control 2005–2016	N = 68 Megaprosthesis reconstruction for proximal femur tumors	X	47 months (12-114 months)	* Overall infection rate 11.8% at mean 25 months: silver 7.9%, control 16.7% (1f). * In late infection, explanted megaprostheses had important degradation of the coating surface (1f). * No differences in functional scores between silver and control (1f). * No local or general signs of toxicity (1f).
Felden 2015 [20]	Prospective cohort 1995–2011	N = 45 Pelvic irradiation before cemented THA	X	51 months (17-137 months)	* Patient survival was 71% at 2y, 52% at 5y and 41% at 10y. * The cumulative probability of revision was 2.2% at 1y, 2.2% at 2y, 8.1% at 5y and 20.2% at 10y. * 6% underwent revision for infection, 1 treated with 2-SR, 2 treated with 1-SR (all successful).
Flint 2007 [2]	Prospective cohort 1989–2004	N = 15 Infection after uncemented Kotz prostheses for bone sarcoma	2-SR	42 months (3-150 months)	* Prosthetic infection occurred at mean 28 months (1-132 months). * 75% CNS, 33% Staph aureus, 8% Pseudomonas aeruginosa, 8% E. coli, 8% Streptococcus viridans (1d). * 73% had second-stage revision: 27% had amputation, 73% with infection control after second-stage. * 60% success with retention of diaphyseal stems; 40% success with removal of anchorage pieces. * No relation between success and anatomical location or infecting organism (1d). * 66% of failures had previous radiation (1c). * In case of infection within 6 months 86% of 2-SR was successful, after 6 months only 25%.

Author and Year	Study Type	Patients	Procedures	Follow-up	Major Outcomes
Funovics 2011 [7]	Retrospective cohort 1982–2008	N = 166 Endoprosthetic reconstruction for tumor	* 83% 1-SR * 8% muscle flap * 8% deceased	47 months (0-365 months)	* Survival rate without infection was 95.9% at 1y, 89.2% at 5y, 89.2% at 10y and 77.8% at 20y. * 7.2% had infection at mean 39 months (0-167 months). * 30% CNS, 30% Staph epidermidis. Polymicrobial infection in 30.8% (1d). * Higher rate of infection in primary tumors, cemented prostheses, pelvic reconstruction, additional operations or radiotherapy (1c). * 63% infection control by 1-SR, 13% additional 1-SR, 25% additional 2-SR.
Gitelis 2008 [21]	No full text	X	X	X	X
Grimer 2002 [3]	Prospective cohort 1989–1998	N = 34 Infection after endoprostheses for sarcoma	2-SR	6-116 months	* Obvious causes of infection included lengthening or rebushing procedures, infected ingrown toenail, chest infection, infected burn blister, infected Hickman catheter and neutropenic septicaemia. * 53% CNS, 32% Staph aureus, 6% streptococci, 3% Enterobacter and 3% Corynebacterium (1d). * 70% had infection control after 2-SR. 6% needed amputation within 6 months. 6% needed additional 2-SR (1 successful, 1 not). 18% had late infections with various treatments. * Overall success rate for controlling infection was 94% at 6 months, 91% at 1 year, 74% at 5 years and 65% at 10 years. * Reinfection occurred in all 3 patients with previous radiotherapy (1c). * Functional outcome after successful infection control was mean 77% MSTS (47-100%).
Hardes 2006 [8]	Retrospective cohort 1992–2003	N = 30 Infection after MUTARS tumor endoprostheses for sarcoma	* 3.3% antibiotics * 10% 1-SR * 80% 2-SR	32 months (3-128 months)	* Infection occurred at mean time 16 months (1-70 months). * 62% CNS, 21% Staph aureus, 14% Enterococcus species. 21% had polymicrobial infections (1d). * 1-SR was successful in 33%, 2-SR in 63% * 33% of 2-SR failures needed amputation, 33% rotationarthroplasty, 11% arthrodesis, 22% retained the spacer (1 died after 4 months, 1 had satisfactory function). * 8.3% needed a change of spacer (1f). * The most important risk factor for failed limb salvage was poor soft tissue. * Chemotherapy, time of occurrence of infection, virulence and type of infection had no influence (1b). * A mean of 2.6 revision operations per patients, mean duration of hospital stay 68 days.

TABLE 2. Evidence table (*Cont.*)

Author and Year	Study Type	Patients	Procedures	Follow-up	Major Outcomes
Hardes 2007 [22]	Prospective cohort 2002–2004	N = 20 Silver-coated MUTARS tumor endoprostheses for metastasis	X	19 months (2-32 months)	* No patients had signs of local or systemic argyrosis (1f). * The mean serum silver concentration was 0.37 ppb preoperatively, 2.80 ppb 2 week postoperatively. Between 2 and 24 months silver concentration varied from 1.93 – 12.98 ppb (1f). * 10 patients showed decreased glomerular filtration rates (1f). * The silver-coating was intact in all patients. Histologic examination showed no signs of chronic inflammation, granulomas or necrotic tissue (1f).
Hardes 2010 [23]	Prospective case-control 2005–2009	N = 51 (74 control) Silver-coated replacement for bone or soft-tissue tumors	Various	19 months (3-63 months)	* 5.9% with silver had infections compared to 17.6% with titanium prostheses, at mean 11 months (1f). * Patients with infection had longer operating time (305 vs. 228 minutes). * 38.5% with titanium prostheses had amputation or rotationplasty for infection, 0% in silver group (1f). * In the silver group 2 were treated with antibiotics alone, 1 had minor revision (one-stage without removal of the stem), all were successful (1f).
Henderson 2011 [24]	Retrospective cohort 1974–2008	N = 2,174 Limb preservation with metallic endoprostheses for tumor	X	X	* 24.5% were considered failures, of which 12% had soft tissue problems, 19% aseptic loosening, 17% fracture, 17% tumor progression, 34% infection. * Infection occurred more often in hinged prostheses than in polyaxial protheses ($p < 0.05$). * Failure incidence decreased over time. The mean time to failure was 47 months. * Literature review of 4359 patients with 29% failures.
Hollinger 1996 [25]	No full text	X	X	X	X
Hsu 1999 [26]	Prospective cohort 1975–1986	N = 38 Limb salvage for tumors needing revision surgery	* 50% revision * 32% amputation * 10% arthrodesis * 8% miscellaneous	51 months	* Indications for reoperation were aseptic loosening (34%), instability (13%), infection (13%), tumor recurrence (13%), fracture (11%) and miscellaneous (16%). * 16% died after revision at a mean of 40 months after revision. * After revision functional results were excellent (12.5%), good (81.3%) or fair (6.25%). * 63% had radiolucent zones immediately after revision. 25% of these developed progressive changes that had an effect on limb function. * Patients with revision had higher survival rates and longer disease-free intervals than patients with amputation ($p < 0.01$). * Overall 18.4% had complications: 5.3% aseptic loosening, 5.3% infection, 2.6% non-union, 2.6% local recurrence and 2.6% instability.
Jacobs 1995 [27]	Retrospective cohort 1983–1991	N = 9 Uncemented THA with previous pelvic irradiation	X	37 months (17-78 months)	* 4/9 radiographic and clinical migrations, 2/4 had revision, of which 1 needed Girdlestone after revision (1c).

TABLE 2. Evidence table (*Cont.*)

Author and Year	Study Type	Patients	Procedures	Follow-up	Major Outcomes
Jeys 2003 [28]	Retrospective cohort 1966–2001	N = 1,261 Endoprostetic replacement	Amputation	5.2 years	* Overall patient survival was 60% at 5 years, 54% at 10 years and 40% at 20 years. * Overall limb survival without amputation was excellent with 91% at 20 years. * Overall risk of amputation was 8.9% of which the reasons were local recurrence (63%), infection (34%), mechanical failure (2%) and persistent pain (1%). * Risk of amputation after infection was 19% compared to 36% for local recurrence. * Time to amputation was a mean of 32 months for infection.
Jeys 2005 [4]	Retrospective cohort 1966–2001	N = 1,240 Prosthetic replacement for bone tumor	* 43% 2-SR * 32% amputation * 24% 1-SR * 2% Girdlestone	5.8 years (0.3-34 years)	* 11% had infection from 1996-2001 3.7%, 14% from 1966-1996. * 88% presented within 2 years after the last surgical procedure. * 48% had Staphylococcus epidermidis, 26% had polymicrobial infection (1d). * Polymicrobial infections did not reduce the rate of successful treatment of infection (1d). * Success rates: amputation 98%, 2-SR 72%, Girdlestone 50%, 1-SR 42%.
Jeys 2007 [29]	Retrospective cohort 1966–2001	N = 412 Endoprosthetic reconstruction for osteosarcoma	X	6.7 years (0-20 years)	* 10% had deep infection at mean time 4.6 months. * 52% had Staph epidermidis, 29% Staph aureus (1d). * There was better survival in patients infected with Staphylococcus (10y survival 92%, mixed organisms 79%, no infection 62.2%, Streptococcus 50%) (1d) * There was no evidence that patients with infections had more effective chemotherapy (1b) * There were more infections after radiotherapy (p=0.02) (1c)
Jeys 2007 [30]	Retrospective cohort 1966–2001	N = 1,254 63 radiotherapy Endoprosthetic replacement for bone tumor	X	5.8 years (0.3-33 years)	* Mean postoperative MSTS function score was lower after radiotherapy (64% vs. 81.3%) (1c) * Risk of infection without radiotherapy 9.8%, preoperative radiotherapy 20.7%, postoperative radiotherapy 35.3% (1c). * Risk of amputation without radiotherapy 7.8%, preoparative radiotherapy 17.2%, postoperative radiotherapy 14.7% (1c). * 10y survival was worse after radiotherapy (29%) than without radiotherapy (58%) (1c).
Jeys 2009 [31]	No full text (chapter book)	X	X	X	X
Kaminsky 2017 [32]	No full text	X	X	X	X
Kim 2007 [33]	Prospective cohort 1997–2003	N = 51 Uncemented THA with irradiation of the pelvis for adenocarcinoma of the prostate	X	4.8 years (2-7.5 years)	* 47% had radiation induced osteonecrosis of the femoral head (1c). * 6% had wound discharge, which healed without surgical treatment (1c). * 2% had deep infection, which required subsequent resection arthroplasty (successful) (1c).

TABLE 2. Evidence table (*Cont.*)

Author and Year	Study Type	Patients	Procedures	Follow-up	Major Outcomes
Lansdown 2010 [34]	Narrative review	X	X	X	* Paper about the mechanisms of absorption and metabolism of silver in the human body, presumed mechanisms of argyria and the elimination of silver-protein complexes in the bile and urine (1f). * Argyria and argyrosis are the principle effects associated with heavy deposition of insoluble silver precipitates in the dermis and cornea/conjunctiva. Argyria is not associated with pathological damage (1f).
Lee 2002 [5]	Retrospective cohort 1985–1998	N = 145 18 infection Tumor prosthesis for bone and soft tissue tumors	* 78% DAIR * 11% 2-SR * 11% 1-SR	44 months (5-136 months)	* 12.4% had infection at mean 8 months (0.5-54 months). * 39% was successfully treated with DAIR or revision; 17% needed arthrodesis and 11% amputation (2). * 100% of 2-SR were successful, 0% of 1-SR were successful. * 33% with uncontrolled infection by DAIR and refused prosthesis removal had suppressive antibiotics. * The knee joint seemed to show poor outcome, but this was not statistically meaningful. * Infection control was poor in cases of cementless fixation ($p < 0.01$). * Chemotherapy gave a higher risk of infection (18.7% vs. 5.6%) (1b). * Soft tissue defects (sinus, pus discharge, wound dehiscence) correlated with poor prognosis ($p < 0.05$).
Li 2011 [35]	Retrospective cohort 1993–2008	N = 53 Endoprosthetic reconstruction for sarcoma	DAIR	10 years	* 1.9% had early infection, successfully treated with DAIR (2). * 5.7% had late infections, all treated with DAIR. One was successful, 2 needed revision (successful) (2). * 7.5% had wound complications requiring repeat surgery (debridement and closure) (2).
Manoso 2006 [16]	Retrospective cohort 1990–2001	N = 11 Infected knee reconstruction after limb-salvage surgery for cancer treated with staged protocol	Staged reconstruction protocol	X	* 82% had chronic infection, with a sinus tract in 45% at mean time 6 months (1-210 months). * 45% had failed DAIRs (2). * 55% had Staph aureus, 27% had Staph epidermidis. In 55%, a single organism caused the infection (1d). * 82% were immunocompromised with the administration of chemotherapy at the time of infection (1b). * All limbs were spared without amputation or flap loss. Overall cure rate was 91%. * Early complications were 2 peroneal palsies and 1 venous flap congestion requiring wound revision. * The mean functional outcome was 23/30 and mean knee range of motion 98 degrees.
Massin 1995 [36]	Excluded	X	X	X	X

TABLE 2. Evidence table (*Cont.*)

Author and Year	Study Type	Patients	Procedures	Follow-up	Major Outcomes
Mavrogenis 2015 [37]	Retrospective cohort 1983–2010	N = 1,161 Megaprosthesis reconstruction after limb salvage surgery for sarcoma	* 83% 2-SR * 12% 1-SR * 5% amputation	Mean 9 years (3-20 years)	* 8.6% had infection at mean time 3.7y. * Most common isolates were Staph epidermidis (47%), Staph aureus (19%) and pseudomonas (6%) (1d). * Overall survival rate of megaprostheses was 88% at 10y and 84% at 20y. * Survival was higher for cementless reconstruction, not different for type of megaprosthesis, site of reconstruction or adjuvant therapy (1b).
Mavrogenis 2011 [38]	Narrative review	X	X	X	* DAIR may be effective in early infections, with short duration of symptoms, well-fixed implants and ideally with well-characterized microbiology demonstrating a highly susceptible pathogen (2). * Success in 2-SR 72-91%, 1-SR 42% and amputation 98-100%. * 2-SR is recommended for persistent infections, antibiotic-resistant pathogens or failed 1-SR. In well-fixed cementless modular prostheses anchorage stems can be retained. * Disadvantages of 2-SR are long hospitalization, increased bone loss, disuse osteoporosis, difficult revision operations and shortening of the affected limb. * Reimplantation should be delayed after completion of chemotherapy (1b). * An antibiotic-loaded cement spacer is essential in 2-SR; added antibiotics should be heatstable (1e). * Most surgeons administer systemic antibiotics 6 weeks, with reimplantation after > 2 months (1a).
McDonald 1990 [39]	Retrospective cohort 1970–1986	N = 304 271 malignant 33 benign Prosthesis or non-biological spacer in limb salvage surgery for primary bone tumors	X	2 years	* 11.8% had infection, 22% of these patients needed amputation. * Adjuvant and neo-adjuvant chemotherapy gave a higher risk of complications (32.8% and 55.4% vs 25.2%). Reconstruction with uncemented prostheses had fewest complications (1b).
Mittermayer 2002 [40]	Excluded	X	X	X	X
Morii 2010 [41]	Retrospective cohort 2000–2008	N = 82 Endoprosthetic reconstruction for knee tumors	X	52 months (9-105 months)	* 17% had infection at mean time 10.9 months. * 50% had Staph aureus, 30% Staph epidermidis and 10% Pseudomonas (1d). * Age, sex, tumor origin, comorbidities, operating time, blood loss, chemotherapy, clean air operating room, extracapsular resection, prosthesis type, number of postoperative antibiotics, posterior muscle flap were not risk factors for infection (1b). * Skin necrosis and surface infection were risk factors for infection.

TABLE 2. Evidence table (*Cont.*)

Author and Year	Study Type	Patients	Procedures	Follow-up	Major Outcomes
Morii 2013 [6]	Retrospective cohort 1995–2009	N = 388 Endoprosthetic reconstruction for knee tumors	* 45% debridement * 14% 2-SR * 10% amputation * 9% 1-SR * 7% soft tissue flap	66 months (5-213 months)	* 14.6% had infection at mean time 13 months. * 47% Staph aureus and 17.5% Staph epidermidis (1d). * Infections were controlled in 84.2% the others had an accepted fistula or suppressive antibiotics. * Patients with diabetes, bone metastasis, lack of gastrocnemius flap coverage and pus required more surgical interventions for infection control. * The most successful therapy was 2-SR (80% success). Therapies with prosthesis removal were more successful than other therapies.
Peel 2014 [9]	Retrospective cohort 1996–2010	N = 121 Tumor endoprostheses surgery	* 53% DAIR * 24% 2-SR * 12% 1-SR * 6% resection * 6% amputation	34 months (17-80 months)	* 14% had infection at median time 18 months * Parenteral antibiotics median 9 days (0-58), 82% received oral combination antibiotic therapy with rifampicin (365 days) (1a). * Success rates: DAIR 75%, 1-SR 100%, 2-SR 50%, resection 0%, amputation 100% (2). * The majority of treatment failures occurred in patients with multi-resistant organisms (1d).
Pilge 2012 [42]	No full text	X	X	X	X
Racano 2013 [43]	Systematic review 1990–2011	N = 4,838 in 48 level IV studies	X	X	* Pooled infection rate was 10% (0-25%). * Most common organisms were Staph aureus and Staph epidermidis (1d). * There is considerable variation in antibiotic regimens. 0-24 hour antibiotic prophylaxis had 13% infection, >24 hour prophylaxis had 8% infection ($p<0.05$) (1a).
Renard 2000 [44]	Prospective cohort 1975–1995	N = 77 Limb saving surgery (50) or ablative surgery (25) for sarcoma	X	97 months (28-271 months)	* 6% had deep infection, leading to amputation in 2/3 cases. * 4% had superficial infection successfully treated with DAIR and gentamicin beads (2).
Sherman 2008 [45]	Excluded	X	X	X	X
Shin 1999 [46]	Retrospective cohort 1970–1990	N = 52 41 malignant 11 benign Limb salvage surgery for musculoskeletal tumor	* 67% revision * 21% amputation * 8% arthrodesis * 2% fibular graft * 2% ORIF	12 years (37-296 months)	* 11.5% had infection. * Functional rating was 63%. Pain 69%, function 53%, emotional acceptance 72%, support 60%, walking ability 62%, gait 54%, hand positioning 66%, manual dexterity 94% and lifting ability 63%. * After revision 33% needed reoperation for complications: 58% aseptic loosening, 25% infection, 17% prosthetic failure and 8% patellar dislocation. * Survival after reoperation was 79% (5y) and 65% (10y).

TABLE 2. Evidence table (*Cont.*)

Author and Year	Study Type	Patients	Procedures	Follow-up	Major Outcomes
Sim 2007 [47]	Retrospective cohort 1996 – 2005	N = 50 Endoprosthetic reconstruction for knee tumors (GRMS)	3 washouts	24.5 months (2-124 months)	* Patients with metastatic disease or pathological fractures did not have higher complication rates. * 12% had deep infection for which patients received multiple washouts and long-term antibiotics (2). * 1/6 had revision; 1/6 had amputation (2).
Wafa 2015 [48]	Prospective case-control 2006–2011	N = 170 Reconstruction with silver-enhanced endoprostheses for several indications	X	12 months	* 11.8% infection in silver group, 22.4% in control group (1f). * Higher incidence of Pseudomonas in the silver group (1d/1f). * 70% of infected prosthesis was successfully treated with DAIR, 31.6% in the control group (1f/2). * 15.3% required implant removal, amputation or antibiotic suppression, 3.5% in the silver group (1f). * 18.8% with adjuvant chemotherapy developed infection (1b). * 15% had relapse infection after 2-SR in the silver group, 42.9% in the control group (1f).
Wirgano-wicz 1999 [49]	Prospective cohort 1980–1995	N = 64 Failed endoprostheses for neoplastic disease	* 75% revision * 25% amputation	2 years	* 13% failed because of an infection. * 50% of infected prostheses had revision with the same prosthesis, 25% with a different prosthesis and 25% underwent amputation. * Patients receiving revision endoprostheses were not at increased risk for a subsequent revision or amputation compared to primary endoprostheses reconstruction.
Zajonz 2016 [50]	Retrospective cohort 1994–2014 Excluded	N = 34 Modular endopros-theses of the lower extremity for infection	X	72 months (6-267 months)	* Reinfection rate after healed reinfection in silver group was 40%, in the non-silver group 57% (1f).
Zajonz 2017 [51]	Retrospective cohort 1994–2011	N = 101 45 tumor Modular endoprostheses of the lower extremity	* 62% 2-SR * 11% resection * 11% arthrodesis * 8% DAIR * 8% amputation	27 months (5-179 months)	* 17.7% had infection (3 early infections, 16 late infections), reinfection rate 37%. * 36.6% CNS, 26.3% Staph epidermidis, 15.8% Staph aureus (1d). * Patients with infection had same age and sex, but higher BMI. * Prosthesis for tumors had fewer infections than other indications (8.9% vs. 21.7%).

of strong levels of evidence published in the form of meta-analyses or randomized controlled trials, we compiled a narrative review discussing various factors associated with infection control in oncologic endoprostheses.

Search Strategy

A literature search was performed in PubMed with relevant search terms on the 23rd of January 2018. The literature search resulted in 83 hits. Additional articles for screening were selected from the reference lists. Articles that were not written in English or did not have full text available were excluded. Twenty-nine articles were excluded based on title and abstract. Another 4 articles were excluded after thorough reading of the full text articles, whereby we included 41 articles in our literature analysis (see Tables 3 and 4).

DAIR procedure is one of the treatment approaches described for PJI of endoprostheses in cancer patients. However, treatment outcomes after DAIR are very variable and unpredictable in an oncology setting. Success rates vary between 39-70% [1,9–12]. Some of the reported factors that are associated with better outcomes after DAIR include superficial early infection, short duration of symptoms, well-fixed implants and well-characterized microbiology demonstrating a highly susceptible pathogen [13–15]. Unfortunately, the studies that reported on DAIR outcomes have very variable periods of clinical follow-up (34 months –10 years).

The most common microorganisms causing infection of oncological endoprostheses are *Staphylococcus aureus* and coagulase negative staphylococci, both account for > 50% of PJI. A large number of the documented infections were also polymicrobial infections accounting for 21-45% of cases [1,4,7,8,16]. There was no difference between monomicrobial and polymicrobial infections regarding outcome [4]. A study by Peel et al. was the only report demonstrating that the majority of infections of endoprosthesis were caused by multi-resistant microorganisms [9]. In one study, the success of outcome for DAIR as well as for two-stage revision for PJI of endoprosthesis did not show any correlation with the infecting organism [2]. It is important to note that the aforementioned results are based on a small number of patients, making generalizability of the findings somewhat limited.

TABLE 3. Exclusion after reading full text article

Author and Year	Reason for Exclusion
Massin, 1995 [36]	No tumorprosthesis, radiation followed by reconstruction with normal prosthesis, 2 late infections (2yr) of 71 cases, both girdlestone
Mittermayer, 2002 [40]	No information on infection, only on aseptic revision in retrospective cohort
Sherman, 2008 [45]	Case report
Zajonz, 2016 [50]	No tumorprostheses, only modular endoprostheses after PJI

TABLE 4. Exclusion after screening abstract and title

2.2. TREATMENT: ONE-STAGE EXCHANGE

Authors: Michiel van de Sande, Hiroyuki Tsuchiya, Daisuke Inoue

QUESTION 1: Does the use of iodine-coated or silver-coated implants make one-stage exchange arthroplasty possible in the management of patients with infected oncologic endoprosthesis?

RECOMMENDATION: Unknown. Current literature has advocated the advantages of surface-modified coating (e.g., silver-coated, iodine-supported implants). Recently, there have been several low-quality, small-scale studies showing promising results for using surface-modified implants in one-stage exchange arthroplasty to treat infected oncologic endoprosthesis. However, to date there remains unsubstantiated evidence and large-scale, high-level evidence studies are necessitated.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

The basic treatment for malignant musculoskeletal tumors is a combination of surgical treatment with adjuvant radiation and chemotherapy. Specifically, limb salvage surgery is becoming the standard treatment for oncologic patients, because the effectiveness of chemotherapy has immensely improved in recent decades [1]. Prosthetic reconstruction using an endoprosthesis provides the best possible level of functionality in patients who require a wide excision for a malignant bone or soft tissue tumor because of improved surgical techniques and implant devices. However, periprosthetic joint infection (PJI) continues to be a serious complication after the placement of an endoprosthesis and is not uncommon to observe [2]. Prior literature has demonstrated that the infection rate of an endoprosthesis ranged from 4-36% [3–6]. Therefore, prevention of PJI becomes an essential task for success, particularly in this patient population. An increasingly popular method used in preventing PJI is the utilization of surface-modified implants with antimicrobial effects, such as iodine-coated or silver-coated implants.

Silver has been widely investigated because of its strong broad-spectrum antibacterial properties, anti-biofilm potential and low cytotoxicity [7–11]. Currently, there are several case series and a few case control studies that examine the success of one-stage revision arthroplasty using silver-coated implants for infected oncologic endoprostheses [12–17]. In a case series of four infected endoprostheses, Zajonz et al. demonstrated that one-stage revision arthroplasty resulted in no subsequent reinfection of the endoprostheses [17]. Wafa et al. [16] conducted a case-control study comparing outcomes for silver-coated prosthesis versus unmodified prosthesis in oncologic patients. In terms of single-stage revisions, they noted a lower rate of infection in the silver group compared to the control group, although this was not statistically significant (5.1% vs. 12.5%; $p = 0.249$). There was, however, a marginally significant decrease in infection rate for two-stage revisions with silver-coated implants (15% vs. 42.9%; $p = 0.05$). Hardes et al. reported that patients who initially underwent placement of a silver-coated prosthesis ($n = 51$) had reduced total infection rates [13]. In addition, the infections that did develop required less aggressive treatment compared to the titanium implant control group ($n = 74$). Similar findings were later produced by the same team for endoprostheses involving the proximal tibia in patients with sarcoma [18].

Iodine-supported implants also exemplify strong inhibition of biofilm formation by preventing antibacterial attachment on metal surfaces similar to silver-coated implants [19–21]. There are three clinical reports that suggest the effectiveness of iodine-supported implants for patients with malignant bone or soft-tissue tumor [19–22]. Shira et al. showed that both one-stage ($n = 11$) and two-stage ($n = 15$) exchange arthroplasty with iodine-supported implants were sufficient to treat infection without need for additional surgery in all cases [19]. However, it is noted that one-stage revision surgery was employed for inactive or quiescent infections and two-stage revision surgery was indicated for active infections (defined by "active sinus discharge or abscess formation or C-reactive protein (CRP) > 0.5 mg/dl"). Nevertheless, there is a need for prospective case-control studies or randomized controlled trials investigating the use of iodine-supported implants in one-stage revision arthroplasty.

In conclusion, it is uncertain whether silver- or iodine-modified implants are effective for one-stage revision arthroplasty in infected oncologic endoprosthesis based on limited literature. There are a few studies in circulation that are promising and advocate for their success in one-stage revision surgery for eradicating infection. This investigative team believes that additional larger-scale investigations involving randomized control trials, prospective cohort and case-control studies are warranted.

QUESTION 2: Is there a role for single-stage exchange arthroplasty for patients with infected oncologic endoprosthesis?

RECOMMENDATION: In principle, despite the lack of sufficient evidence, single-stage exchange arthroplasty can be performed in patients with infected oncologic endoprosthesis if the general requirements to perform a single-stage procedure are fulfilled. However, a single-stage revision without removing the anchorage components is not recommended, since better infection control can be achieved when prostheses were removed rather than salvaged.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Periprosthetic joint infections (PJIs) are serious complications of reconstruction of defects created by tumor resection. The reconstruction in tumor surgery usually involves the use of modular endoprostheses. Infection following tumor surgery and reconstruction is relatively common, occurring in 8 to 35% of primary implants [1–3]. As limb salvage surgery has gained popularity over the recent years, the number of reconstruction procedures after tumor resection, and the ensuing infections, have increased [1–3].

Despite the high incidence of PJI following oncologic reconstruction, and perhaps because of the relatively low volume of tumor reconstruction cases, there is a universal lack of high-quality studies related to PJI following oncologic reconstructions. The review of current available literature reveals only 12 relevant articles on infections following oncologic reconstructions using tumor endoprostheses. Only six published articles reported the outcomes of single-stage exchange arthroplasty [2,4–8]. However, it must be noted that some of the authors perform a single-stage revision with removal of all exchangeable and polyethylene components with debridement of surrounding soft tissues but without removal of the fixation anchoring components [2,4–8].

As presented by Buchholz et al. in the 1970s, the concept of classic single-stage exchange arthroplasty after infected total joint replacement is the radical debridement and removal of all foreign materials [9]. Morii et al. found that infection control rates were significantly higher when prostheses were removed rather than salvaged in a series of 57 patients with PJI of tumor endoprostheses [4]. According to Hardes et al., an optimal soft tissue condition is imperative for a successful limb salvage procedure [7].

Currently, there is no concrete evidence in the literature to answer the question, "What role, if any, does one-stage exchange arthroplasty play in the management of PJI after oncologic reconstruction using modular endoprostheses?" However, borrowing from the hip and knee adult reconstruction literature, one can state that the rate of infection control is usually better when all prosthetic and foreign material are removed and new implants used either at the same time (one-stage exchange) or at a later date. It is also an agreed principle that the rate of infection control correlates with the extent of debridement and bioburden reduction. Applying these principles, we can state that one-stage exchange arthroplasty does have a role in the management of acute or chronic PJI following oncologic reconstruction. The question that remains and is somewhat unique to oncologic reconstruction is whether all foreign material needs to be removed during one-stage exchange or some parts, such as the anchoring portion of the prosthesis in the bone, can be retained. The tendency would be to advocate that all foreign material should be removed during one-stage exchange. However, removal of the anchoring part of the prosthesis may not be possible or removal of this part may preclude a later reconstruction. Under these circumstances, sub-radical resection arthroplasty may be performed. It is critical, however, that the retained prosthesis is cleaned physi-

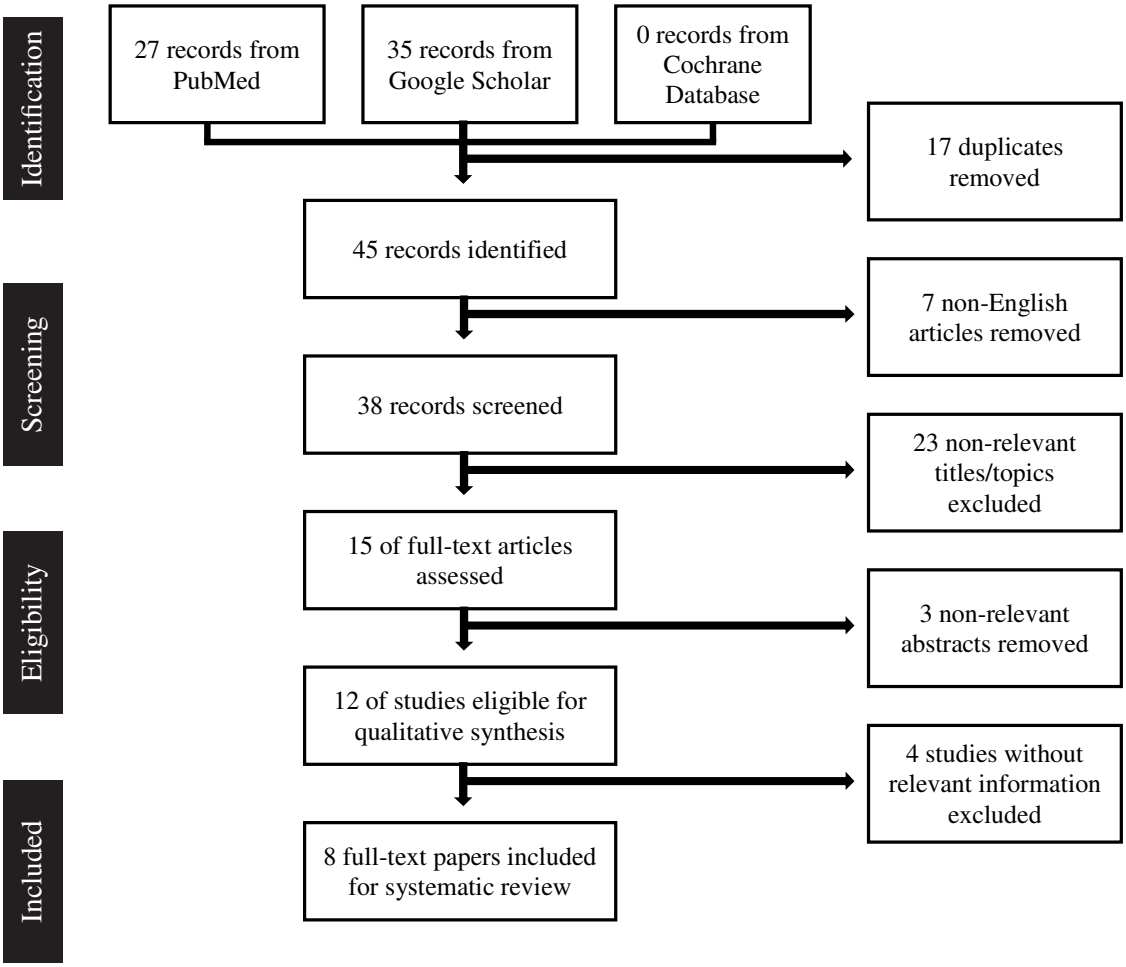

FIGURE 1. PRISMA Flowchart showing the identification of relevant studies during the review process.

cally and chemically with agents such as chlorhexidine or povodine iodine scrubs and washed thoroughly. Obeying the general principle of infection surgery is likely to allow some patients with infected oncologic prostheses to be treated by one-stage exchange arthroplasty. Future research is needed to determine which group of patients would most benefit from one-stage exchange arthroplasty versus two-stage exchange arthroplasty.

2.3. TREATMENT: RESEARCH CAVEATS

Authors: Germán Luis Farfalli, Peter Choong, Sam Francis

QUESTION 1: Should the management of periprosthetic joint infection (PJI) involving an oncologic endoprosthesis differ from that of conventional joint replacement prostheses?

RECOMMENDATION: No. The management of PJI involving an oncologic endoprosthesis is similar to that of conventional joint replacement prosthesis.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Deep infection of primary total joint arthroplasty (TJA) is a catastrophic complication. However, the infection rate is relatively low [1]. Tumor endoprosthesis are essentially larger implants similar to those used in total joint replacements, although the type of surgery and the risk factors related to the type of patient differ significantly [2,3]. Therefore, a deep infection with these types of implants drastically worsens the prognosis of the affected limb and significantly increases the risk of amputation compared to conventional prosthetic arthroplasties [2,3].

Despite these differences in the rate of complications between primary arthroplasties and endoprostheses, the management of postoperative infections is similar. There is a general consensus that infections are divided into either early or late infections, according to the time of diagnosis [4–9].

Despite the large amount of literature analyzing PJIs, there are no comparative studies between management and outcomes nor between primary prostheses and endoprosthesis. There are only a limited number of retrospective studies focused on the outcomes of periprosthetic infections in endoprostheses [10–13]. Therefore, the management of infections in endoprostheses is based on protocols used in primary prostheses. A new strategy that seems to be improving the results at the time of endoprostheses re-implant is silver-coated endoprostheses. Wafa et al. [14] suggests in a retrospective case-control study that the overall success rates in controlling infection by two-stage revision in patients treated with silver-coated endoprosthesis was 85%, compared to uncoated tumor prostheses ($p = 0.05$, Chi-square test). The Agluna-treated endoprostheses were associated with a lower rate of early periprosthetic infection. In addition, these silver-treated implants were particularly useful in two-stage revisions for infection and in those patients with incidental positive cultures at the time of implantation of the prosthesis. Finally, they conclude that debridement with antibiotic treatment and retention of the implant appeared to be more successful with silver-coated implants.

There is no consensus in the management of an infected endoprosthesis given the limited data. The current recommendation is based on treatment of infected primary arthroplasties.

2.4. TREATMENT: TWO-STAGE EXCHANGE

Authors: Paul Jutte, Hesham Abdelbary, Claudia Löwik

QUESTION 1: What factors may improve the outcome of a two-stage exchange arthroplasty in patients with an infected oncologic endoprosthesis?

RECOMMENDATION: There are numerous factors that improve the outcome of two-stage exchange arthroplasty in general, and after oncologic reconstruction in particular. These include host-related factors (such as host optimization by treating anaemia, malnutrition, hyperglycemia, immunosuppressive state and so on), organism-related factors (such as administration of appropriate systemic and local antibiotics) and surgery-related factors (such as aggressive debridement of soft tissue and bone, optimal soft tissue management and prevention of postoperative complications).

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Surgical reconstruction using a mega-endoprosthesis after tumor resection can be frequently associated with deep surgical site infection that leads to prosthetic joint infection (PJI). The prevalence of PJI associated with oncologic endoprosthesis is 7-28% compared to only 1-2% in primary joint replacements. Cancer patients are at a higher risk for developing PJI after receiving an endoprosthesis due to numerous risk factors, which lead to local and systemic immunodeficiency. These risk factors include chemotherapy, radiotherapy, prolonged surgical time, increased bleeding, larger implant surface area and compromised soft tissue envelope.

In case of an infected oncologic endoprosthesis, debridement, antibiotics and implant retention (DAIR) can be performed, especially in early acute infections (< 3 months). If DAIR fails to eradicate the infection, a two-stage revision is necessary. In literature, two-stage revision is generally reported as a good surgical approach for infection control with a reported success rate of 63-100% [1–6]. Eradication of infection is generally worse after a single-stage revision and, of course, better after an amputation [4,7–9].

Although various studies assessed infection after oncologic endoprostheses, only a few have specifically evaluated the efficacy of DAIR or two-stage revision [2,3]. The factors associated with infection control in oncologic endoprostheses have been individually discussed. After review of the literature, 41 articles were included in our literature analysis. The most important study characteristics are described in the evidence table.

Antibiotics

Little is known about the use of antibiotics in two-stage revision for an infected oncologic endoprostheses. In all studies, antibiotic regimens differed per patient according to culture results and local protocol without specific details being provided. In general, antibiotics should be administered for three months, and the type of antibiotics is decided based on culture results, as well as the consultation with an infectious disease specialist. There are no studies stating that administering antibiotics longer than three months is necessary. Regarding antibiotic prophylaxis, it is recommended to administer prophylactic antibiotics for more than 24 hours, since a systematic review of Racano et al. showed that this reduces the infection rate from 13% to 8% [10]. Regarding the timing for reimplantation after PJI treatment, there is no evidence for the optimal timing other than waiting for completion of chemotherapy before reimplantation [11].

Chemotherapy

The influence of chemotherapy can be expected since it down regulates the host defence mechanisms. However, this is not uniformly reported in the assessed studies. Several studies found an increased risk of developing an infection after implantation of an oncologic endoprostheses in patients undergoing chemotherapy [5,11,12]. However, other studies did not confirm this notion [8,13,14]. Because of the immunocompromised status of patients receiving chemotherapy, it is advised to delay reimplantation until after completion of chemotherapy [15].

Radiotherapy

Application of radiotherapy increases the risk of infection after oncologic endoprosthesis [7,16]. Grimer et al. and Flint et al. found a higher failure rate in patients who underwent radiotherapy [2,3]. Regarding timing of radiotherapy, postoperative radiation has a bigger influence on the infection rate than preoperative radiotherapy [16]. The success rate of DAIR procedures in which postoperative radiotherapy had been applied was lower. Radiation influences the quality of soft tissue and hampers local defence mechanisms.

Microorganisms

The most common microorganisms causing infection of oncological endoprostheses are *Staphylococcus aureus* and coagulase negative staphylococci that account for > 50% of PJI. Many of the documented infections were also polymicrobial infection accounting 21-45% of cases [1,4,7,8,17]. There was no difference between monomicrobial and polymicrobial infections regarding cure rate [4]. A study by Peel et al. demonstrated that the majority of infections were caused by multi-resistant microorganisms [9]. Cure rates for DAIR as well as for two-stage revision after PJI did not show any correlation between the infecting organism and the success of eradicating the infection [2]. It is important to note that the aforementioned results are based on a small number of patients. Therefore, it is difficult to draw firm conclusions that can be generalized to all cases of infection associated with oncologic endoprostheses.

Silver-coated Arthroplasty

Few studies have reported on the benefits of using silver-coated endoprostheses to decrease the risk of developing PJI in patients

treated for primary and metastatic bone cancer. Silver cations possess bactericidal properties by disrupting cellular membrane and DNA formation. Donati et al. and Wafa et al. reported a 50% less incidence of PJI in patients treated with silver-coated megaprosthesis compared to uncoated ones [12,18]. In addition, Wafa et al. showed that the success rate of using DAIR as well as two-stage revision to treat infected silver-coated megaprosthesis was significantly higher than when used to treat infected uncoated implants [12]. Zajonz et al. reported that reinfection rate after healed reinfection in the silver group was slightly better than the non-silver group (40 vs. 57%) [19].

Hardes et al. showed that silver levels in the serum were detected up to 24 months post implantation of sliver-coated prostheses [20]. Also, there were no reports of toxicity or adverse local tissue reaction in patients treated with silver-coated implants. Despite these promising results, there are only a handful of studies that reported on outcomes after using these coated implants.

DAIR

The DAIR procedure is one of the treatment approaches described for PJI of endoprostheses in cancer patients. However, treatment outcomes after DAIR are highly variable and unpredictable in an oncology setting. Success rates vary between 39-70% [1,9,12,17,21]. Reported factors that are associated with better outcomes after DAIR include superficial early infection, short duration of symptoms, well-fixed implants and well-characterized microbiology demonstrating a highly susceptible pathogen [13,15,22]. Unfortunately, the studies that reported on DAIR outcomes have a highly variable period of clinical follow-up (34 months–10 years).

TABLE 1. Evidence table

Author and Year	Study Type	Patients	Procedures	Follow-up	Major Outcomes
Bus 2017 [21]	Retrospective cohort 2008–2014	N = 47 LUMIC reconstruction for pelvic tumor	* 69% DAIR * 31% implant removal	3.9 years	* 28% had infection. * 69% were successfully treated with DAIR (2). * 31% needed implant removal. Two had amputation, 1 rotationplasty and 1 LUMIC prosthesis. * More blood loss was associated with a higher risk of infection; other factors were not associated.
Chambers 1962 [23]	Narrative review	X	X	X	* Article on the bactericidal effects of silver (1f).
Dhanoa 2015 [1]	Retrospective cohort 2007–2011	N = 105 Endoprosthetic reconstruction for tumor	* 54% DAIR * 46% 2-SR	32 months	* 12.4% infection at 0-63 months. * Higher risk after additional procedures (13x), comorbidity, proximal tibia endoprostheses, pelvic endoprostheses and preoperative hospitalization >48 hour. Lower risk with distal femoral prostheses. * 80% of infections had operations >2.5h, compared to 16.3% in non-infections. * 38% *Staph aureus*, 31% CNS, 23% Klebsiella pneumoniae, 23% Pseudomonas aeruginosa. 38.5% had polymicrobial infection (1d). * 80% of 2-SR were successful; 1 patient had antibiotic suppression. * 43% of DAIR were successful; 2 patients had antibiotics; 2 patients had amputation (2).
Donati 2016 [18]	Retrospective case-control 2005–2016	N = 68 Megaprosthesis reconstruction for proximal femur tumors	X	47 months (12-114 months)	* Overall infection rate 11.8% at mean 25 months: silver 7.9%, control 16.7% (1f). * In late infection, explanted megaprostheses had important degradation of the coating surface (1f). * No differences in functional scores between silver and control (1f). * No local or general signs of toxicity (1f).
Felden 2015 [24]	Prospective cohort 1995–2011	N = 45 Pelvic irradiation before cemented THA	X	51 months (17-137 months)	* Patient survival was 71% at 2y, 52% at 5y and 41% at 10y. * The cumulative probability of revision was 2.2% at 1y, 2.2% at 2y, 8.1% at 5y and 20.2% at 10y. * 6% underwent revision for infection, 1 treated with 2-SR, 2 treated with 1-SR (all successful).
Flint 2007 [2]	Prospective cohort 1989–2004	N = 15 Infection after uncemented Kotz prostheses for bone sarcoma	2-SR	42 months (3-150 months)	* Prosthetic infection occurred at mean 28 months (1-132 months). * 75% CNS, 33% *Staph aureus*, 8% Pseudomonas aeruginosa, 8% E. coli, 8% Streptococcus viridans (1d). * 73% had second-stage revision: 27% had amputation, 73% with infection control after second-stage. * 60% success with retention of diaphyseal stems; 40% success with removal of anchorage pieces. * No relation between success and anatomical location or infecting organism (1d). * 66% of failures had previous radiation (1c). * In case of infection within 6 months 86% of 2-SR was successful, after 6 months only 25%.

TABLE 1. Evidence table (*Cont.*)

Author and Year	Study Type	Patients	Procedures	Follow-up	Major Outcomes
Funovics 2011 [7]	Retrospective cohort 1982–2008	N = 166 Endoprosthetic reconstruction for tumor	* 83% 1-SR * 8% muscle flap * 8% deceased	47 months (0-365 months)	* Survival rate without infection was 95.9% at 1y, 89.2% at 5y, 89.2% at 10y and 77.8% at 20y. * 7.2% had infection at mean 39 months (0-167 months). * 30% CNS, 30% Staph epidermidis. Polymicrobial infection in 30.8% (1d). * Higher rate of infection in primary tumors, cemented prostheses, pelvic reconstruction, additional operations or radiotherapy (1c). * 63% infection control by 1-SR, 13% additional 1-SR, 25% additional 2-SR.
Gitelis 2008 [25]	No full text	X	X	X	X
Grimer 2002 [3]	Prospective cohort 1989–1998	N = 34 Infection after endoprostheses for sarcoma	2-SR	6-116 months	* Obvious causes of infection included lengthening or rebushing procedures, infected ingrown toenail, chest infection, infected burn blister, infected Hickman catheter and neutropenic septicaemia. * 53% CNS, 32% *Staph aureus*, 6% streptococci, 3% Enterobacter and 3% Corynebacterium (1d). * 70% had infection control after 2-SR. 6% needed amputation within 6 months. 6% needed additional 2-SR (1 successful, 1 not). 18% had late infections with various treatments. * Overall success rate for controlling infection was 94% at 6 months, 91% at 1 year, 74% at 5 years and 65% at 10 years. * Reinfection occurred in all 3 patients with previous radiotherapy (1c). * Functional outcome after successful infection control was mean 77% MSTS (47-100%).
Hardes 2006 [8]	Retrospective cohort 1992–2003	N = 30 Infection after MUTARS tumor endoprostheses for sarcoma	* 3.3% antibiotics * 10% 1-SR * 80% 2-SR	32 months (3-128 months)	* Infection occurred at mean time 16 months (1-70 months). * 62% CNS, 21% *Staph aureus*, 14% Enterococcus species. 21% had polymicrobial infections (1d). * 1-SR was successful in 33%, 2-SR in 63% * 33% of 2-SR failures needed amputation, 33% rotationarthroplasty, 11% arthrodesis, 22% retained the spacer (1 died after 4 months, 1 had satisfactory function). * 8.3% needed a change of spacer (1f). * The most important risk factor for failed limb salvage was poor soft tissue. * Chemotherapy, time of occurrence of infection, virulence and type of infection had no influence (1b). * A mean of 2.6 revision operations per patients, mean duration of hospital stay 68 days.
Hardes 2007 [20]	Prospective cohort 2002–2004	N = 20 Silver-coated MUTARS tumor endoprostheses for metastasis	X	19 months (2-32 months)	* No patients had signs of local or systemic argyrosis (1f). * The mean serum silver concentration was 0.37 ppb preoperatively, 2.80 ppb 2 week postoperatively. Between 2 and 24 months silver concentration varied from 1.93 – 12.98 ppb (1f). * 10 patients showed decreased glomerular filtration rates (1f). * The silver-coating was intact in all patients. Histologic examination showed no signs of chronic inflammation, granulomas or necrotic tissue (1f).

TABLE 1. Evidence table (*Cont.*)

Author and Year	Study Type	Patients	Procedures	Follow-up	Major Outcomes
Hardes 2010 [26]	Prospective case-control 2005–2009	N = 51 (74 control) Silver-coated replacement for bone or soft-tissue tumors	Various	19 months (3-63 months)	* 5.9% with silver had infections compared to 17.6% with titanium prostheses, at mean 11 months (1f). * Patients with infection had longer operating time (305 vs. 228 minutes). * 38.5% with titanium prostheses had amputation or rotationplasty for infection, 0% in silver group (1f). * In the silver group 2 were treated with antibiotics alone, 1 had minor revision (one-stage without removal of the stem), all were successful (1f).
Henderson 2011 [27]	Retrospective cohort 1974–2008	N = 2,174 Limb preservation with metallic endoprostheses for tumor	X	X	* 24.5% were considered failures, of which 12% had soft tissue problems, 19% aseptic loosening, 17% fracture, 17% tumor progression, 34% infection. * Infection occurred more often in hinged prostheses than in polyaxial protheses ($p < 0.05$). * Failure incidence decreased over time. The mean time to failure was 47 months. * Literature review of 4359 patients with 29% failures.
Hollinger 1996 [28]	No full text	X	X	X	X
Hsu 1999 [29]	Prospective cohort 1975–1986	N = 38 Limb salvage for tumors needing revision surgery	* 50% revision * 32% amputation * 10% arthrodesis * 8% miscellaneous	51 months	* Indications for reoperation were aseptic loosening (34%), instability (13%), infection (13%), tumor recurrence (13%), fracture (11%) and miscellaneous (16%). * 16% died after revision at a mean of 40 months after revision. * After revision functional results were excellent (12.5%), good (81.3%) or fair (6.25%). * 63% had radiolucent zones immediately after revision. 25% of these developed progressive changes that had an effect on limb function. * Patients with revision had higher survival rates and longer disease-free intervals than patients with amputation ($p < 0.01$). * Overall 18.4% had complications: 5.3% aseptic loosening, 5.3% infection, 2.6% non-union, 2.6% local recurrence and 2.6% instability.
Jacobs 1995 [30]	Retrospective cohort 1983–1991	N = 9 Uncemented THA with previous pelvic irradiation	X	37 months (17-78 months)	* 4/9 radiographic and clinical migrations, 2/4 had revision, of which 1 needed Girdlestone after revision (1c).

TABLE 1. Evidence table (*Cont.*)

Author and Year	Study Type	Patients	Procedures	Follow-up	Major Outcomes
Jeys 2003 [31]	Retrospective cohort 1966–2001	N = 1,261 Endoprostetic replacement	Amputation	5.2 years	* Overall patient survival was 60% at 5 years, 54% at 10 years and 40% at 20 years. * Overall limb survival without amputation was excellent with 91% at 20 years. * Overall risk of amputation was 8.9% of which the reasons were local recurrence (63%), infection (34%), mechanical failure (2%) and persistent pain (1%). * Risk of amputation after infection was 19% compared to 36% for local recurrence. * Time to amputation was a mean of 32 months for infection.
Jeys 2005 [4]	Retrospective cohort 1966–2001	N = 1,240 Prosthetic replacement for bone tumor	* 43% 2-SR * 32% amputation * 24% 1-SR * 2% Girdlestone	5.8 years (0.3-34 years)	* 11% had infection from 1996-2001 3.7%, 14% from 1966-1996. * 88% presented within 2 years after the last surgical procedure. * 48% had Staphylococcus epidermidis, 26% had polymicrobial infection (1d). * Polymicrobial infections did not reduce the rate of successful treatment of infection (1d). * Success rates: amputation 98%, 2-SR 72%, Girdlestone 50%, 1-SR 42%.
Jeys 2007 [32]	Retrospective cohort 1966–2001	N = 412 Endoprosthetic reconstruction for osteosarcoma	X	6.7 years (0-20 years)	* 10% had deep infection at mean time 4.6 months. * 52% had Staph epidermidis, 29% Staph aureus (1d). * There was better survival in patients infected with Staphylococcus (10y survival 92%, mixed organisms 79%, no infection 62.2%, Streptococcus 50%) (1d). * There was no evidence that patients with infections had more effective chemotherapy (1b). * There were more infections after radiotherapy (p=0.02) (1c).
Jeys 2007 [16]	Retrospective cohort 1966–2001	N = 1,254 63 radiotherapy Endoprosthetic replacement for bone tumor	X	5.8 years (0.3-33 years)	* Mean postoperative MSTS function score was lower after radiotherapy (64% vs. 81.3%) (1c). * Risk of infection without radiotherapy 9.8%, preoperative radiotherapy 20.7%, postoperative radiotherapy 35.3% (1c). * Risk of amputation without radiotherapy 7.8%, preoparative radiotherapy 17.2%, postoperative radiotherapy 14.7% (1c). * 10y survival was worse after radiotherapy (29%) than without radiotherapy (58%) (1c).

TABLE 1. Evidence table (*Cont.*)

Author and Year	Study Type	Patients	Procedures	Follow-up	Major Outcomes
Kim 2007 [35]	Prospective cohort 1997–2003	N = 51 Uncemented THA with irradiation of the pelvis for adenocarcinoma of the prostate	X	4.8 years (2-7.5 years)	* 47% had radiation induced osteonecrosis of the femoral head (1c). * 6% had wound discharge, which healed without surgical treatment (1c). * 2% had deep infection, which required subsequent resection arthroplasty (successful) (1c).
Lansdown 2010 [36]	Narrative review	X	X	X	* Paper about the mechanisms of absorption and metabolism of silver in the human body, presumed mechanisms of argyria and the elimination of silver-protein complexes in the bile and urine (1f). * Argyria and argyrosis are the principle effects associated with heavy deposition of insoluble silver precipitates in the dermis and cornea/conjunctiva. Argyria is not associated with pathological damage (1f).
Lee 2002 [5]	Retrospective cohort 1985–1998	N = 145 18 infection Tumor prosthesis for bone and soft tissue tumors	* 78% DAIR * 11% 2-SR * 11% 1-SR	44 months (5-136 months)	* 12.4% had infection at mean 8 months (0.5-54 months). * 39% was successfully treated with DAIR or revision; 17% needed arthrodesis and 11% amputation (2). * 100% of 2-SR were successful, 0% of 1-SR were successful. * 33% with uncontrolled infection by DAIR and refused prosthesis removal had suppressive antibiotics. * The knee joint seemed to show poor outcome, but this was not statistically meaningful. * Infection control was poor in cases of cementless fixation ($p < 0.01$). * Chemotherapy gave a higher risk of infection (18.7% vs. 5.6%) (1b). * Soft tissue defects (sinus, pus discharge, wound dehiscence) correlated with poor prognosis ($p < 0.05$).
Li 2011 [22]	Retrospective cohort 1993–2008	N = 53 Endoprosthetic reconstruction for sarcoma	DAIR	10 years	* 1.9% had early infection, successfully treated with DAIR (2). * 5.7% had late infections, all treated with DAIR. One was successful, 2 needed revision (successful) (2). * 7.5% had wound complications requiring repeat surgery (debridement and closure) (2).
Manoso 2006 [17]	Retrospective cohort 1990–2001	N = 11 Infected knee reconstruction after limb-salvage surgery for cancer treated with staged protocol	Staged reconstruction protocol	X	* 82% had chronic infection, with a sinus tract in 45% at mean time 6 months (1-210 months). * 45% had failed DAIRs (2). * 55% had Staph aureus, 27% had Staph epidermidis. In 55%, a single organism caused the infection (1d). * 82% were immunocompromised with the administration of chemotherapy at the time of infection (1b). * All limbs were spared without amputation or flap loss. Overall cure rate was 91%. * Early complications were 2 peroneal palsies and 1 venous flap congestion requiring wound revision. * The mean functional outcome was 23/30 and mean knee range of motion 98 degrees.

QUESTION 2: What is the best reconstruction technique for an infected allograft?

RECOMMENDATION: The best reconstruction technique for an infected allograft is resection of the infected allograft and reconstruction (preferable two-stage) with an endoprosthesis.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 93%, Disagree: 0%, Abstain: 7% (Super Majority, Strong Consensus)

RATIONALE

Use of allograft in the reconstruction of a massive bone defect created by resection of a tumor is frequently successful. However, as with all tumor reconstruction methods, it is also plagued with complications, infection being one of them. A number of observational studies have been published on the subject. The largest case series by Mankin et al. described 121 allograft infections in 945 patients accounting to an infection rate of 12.8% [1]. The study did not, however, address management of the infected allograft. A more recent systematic review by Aponte et al. [2] reviewed the available literature and infection rates reported in previous studies [3–7]. The infection rate of allograft used after tumor resection ranged from 8.5% to 13.3%. The infection rate in their own series was 9% with 60 infections in 673 patients who received massive allografts after oncological resections. Only 18% (11/60) of the patients in that cohort were successfully treated by debridement and antibiotics with salvage of the original allograft. Of the 41 patients who underwent two-stage revision, 24 were revised with allograft and 17 with endoprostheses. Reinfection occurred in 14 patients of which 12 were in the allograft group and 2 were in the endoprostheses group. This demonstrated a lesser rate of reinfection when revision to endoprostheses was done as opposed to revision to another allograft.

Our search did not find any reports of revision to a vascularized fibular autograft or treatment with bone transport. Although these are both biological methods of reconstruction and their efficacy in the treatment of bone defects created by trauma and infection as well as for primary reconstruction following tumor resection is well established [8,9].

QUESTION 3: What is the best surgical treatment for management of a chronically infected oncologic endoprosthesis? Does this change if the patient is receiving or has received recent chemotherapy and/or irradiation?

RECOMMENDATION: We recommend a two-stage revision in the management of a chronically infected oncologic endoprosthesis; however, we acknowledge that support for a one-stage exchange is increasing. There is no study to suggest that this recommendation should change if the patient is receiving or has received recent chemotherapy and/or irradiation.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 93%, Disagree: 0%, Abstain: 7% (Super Majority, Strong Consensus)

RATIONALE

Although the use of an endoprosthesis in the treatment of musculoskeletal tumors has many advantages, infection of the endoprosthetic device is a significant complication. In addition to eradicating the infection, the goal in treating these infections is to salvage the limb and avoid amputation. There are numerous interventions used in the management of an endoprosthetic infection, including irrigation and debridement, one-stage revision, two-stage revision and amputation as a last resort.

Jeys et al. demonstrated that two-stage revision was able to eradicate infection in 42 of 58 patients (72%), compared to a 47% (15 of 32) success rate with one-stage revision and a 6% (4 of 68) success rate with local surgical debridement with or without antibiotics [1]. Morii et al. reinforce the idea that two-stage revisions have better outcomes compared to both a one-stage exchange and irrigation and debridement [2]. Finally, investigators in Malaysia reported an 80% success rate with two-stage revision compared to a 42.8% success rate with surgical debridement without a change of the implant [3].

In addition to greater success rates, two-stage revision has demonstrated greater functional outcomes. Grimer et al. assessed the functional outcome of patients with a successful two-stage revision using the Musculoskeletal Tumor Society functional evaluation score. The scores ranged from 47% to 100% with a mean of 77% [4]. One study reviewed one-stage exchange which demonstrated a 77.8% success rate and suggested that one-stage revision of infected megaprostheses without exchange of anchorage components is a sensible and useful choice for patients with antibiotic-sensitive microorganisms [5].

Given these results, we have concluded that two-stage revision is currently more supported by literature as a surgical treatment for the management of a chronically infected oncologic endoprosthesis. However, due to the presence of some conflicting data, the strength of this recommendation is limited, and we do believe that one-stage exchange with or without exchange of anchorage components may represent a feasible option.

Authors: Carlos A. Sánchez Correa, Mustafa Citak, Carl Haasper, Niklas Unter Ecker

QUESTION 1: What is the relationship between smoking and infection in fracture procedures? Is smoking history or only current smoking important? Does nicotine cessation at time of fracture reduce complication rates?

RECOMMENDATION: Smoking seems to increase the risk of infection in fracture procedures. The importance of smoking history versus current smoking status is unknown. It is also unknown if nicotine cessation (smoking) at time of fracture treatment reduces complication rates.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Smoking has been seen to have a negative effect in physiological and biological pathways. It interferes with the coagulation cascade (smokers clot faster), it impairs vascular function, and also interferes with the immune system (alters neutrophil function, migration and action) [1–5]. Even after smoking cessation, neutrophil phagocytic function continues to be impaired. Monocyte and macrophage correct function are key to prevent infection caused by *S. aureus* or *E. coli*, two of the most common infection-causing pathogens [3,4]. Smoking also affects the proliferative and remodelling phases of healing [6] by compromising epidermal regeneration and neovascularization and by causing decrease in perfusion and oxygenation [7,8].

The relationship between smoking and complications after fracture procedures has been widely studied [9,10]. Available literature suggests that smoking increases the overall incidence of complications including the risk for non-union and surgical site infection (SSI) [9–14]. Although the latter has not been consistent throughout studies, many authors continue to investigate this relationship.

Some available studies have not found smoking to be a definitive risk factor for infection [9–14]. One case control study that compared 140 smoking and 133 non-smoking patients with open tibia fractures suggested that infection might be multifactorial and not related to a single event [11]. A different prospective cohort study evaluating patients with limb-threatening open tibia fractures showed that current smokers were twice as likely to develop an infection compared to non-smokers (odds ratio (OR) 2.2; $p = 0.05$) [12]. That same study observed that previous smokers, compared to non-smokers, did not show any difference in terms of infection risk (OR 1.00; $p = 0.99$). Court-Brown et al. evaluated 178 patients who underwent fixation after calcaneal fractures [15]. They evaluated factors associated with infection including time to surgery, level of experience of the attending, smoking and type of wound closure. None of these were shown to be associated with infection. A randomized control trial allocated 105 smokers with a fracture requiring surgical treatment to a quit-smoking group ($n = 50$) or a non-quit-smoking group ($n = 55$) [16]. They found that the odds for presenting with a complication (superficial infection being the most common) was 2.51 times higher in the group that continued smoking compared to those who quit smoking, although this did not reach statistical significance. With similar findings, a recent systematic review found that there was no increased risk in smokers either for superficial or deep infection ($p = 0.13$ and $p = 0.33$, respectively) [14]. In terms of deep infection, retrospective studies have evaluated intramedullary nailing of tibia shaft fractures [17], open reduction and internal fixation (ORIF) of pilon fractures [18] and ORIF of acetabular fractures [19]. These concluded that there is no statistical significance related to smoking and increased infection rates. The most recent published study also showed that there was no statistically significant increased risk of infection in relation to smoking ($p = 0.45$) [20].

There is also evidence suggesting that smoking clearly increases the risk of infection in fracture procedures. Nasell et al. [13] evaluated 906 patients with ankle fractures that developed deep wound infections. They reported that these were more likely to be smokers than non-smokers (4.9% versus 0.8%; $p < 0.001$). They concluded that smoking was a risk factor associated with both deep and superficial wound infections (OR 6.0 and 1.7, respectively). Morris et al. [21] published a retrospective cohort study that included 302 bicondylar tibia plateau fractures treated with ORIF. Smoking was identified as the most important risk factor for deep infection (OR 2.40; $p = 0.02$). That same year Ovaska et al. [22] published a prospective cohort study that included 1,923 ankle surgeries with 131 deep surgical site infections. Smoking was shown to be statistically significant relative to infection in both the univariate (OR 4.0; $p = 0.004$) and multivariate analyses (OR 4.1; $p = 0.017$).

Two additional studies evaluated smoking-related complications in lower limb fractures. One consisted of a retrospective cohort study that included 519 patients with distal tibia fractures [23]. Smoking was associated with overall complications including infection (OR 3.40; $p = 0.039$). The second evaluated 30-day postoperative complications after ankle fracture fixation in a prospective cohort study [24]. They concluded that among the predictors for major local complications (deep wound infection and reoperation) peripheral vascular disease, open wound, contaminated wound classification and smoking (OR 2.85; $p = 0.0031$) were the strongest. Evidence from the last two years reveal smoking as an independent risk factor for

wound infection, as presented in a retrospective study managing 1,320 elbow fractures [25] and a case-control study from 318 calcaneal fractures [26]. In the first study, only smoking was found to have an association with infection after multivariate analysis (adjusted OR = 2.2; p = 0.023); the second study revealed that higher body mass index, delayed operation and active smoking (OR 19.497, p < .001) represented an increased risk for wound infection after ORIF.

Despite the conflicting evidence found in the literature, smoking seems to have a negative effect on overall complications and health and could potentially lead to an increased risk of infection. It is well-established that smoking has a detrimental effect on tissue healing and cellular pathways. Nonetheless, the current literature lacks the high-level evidence to state a direct relationship between these two factors. The recommendation provided here is inconclusive.

QUESTION 2: What is the role of nutritional supplementation (NS) in avoiding infection in acute fracture cases?

RECOMMENDATION: (1) Evidence does not support the role of NS for avoiding infections in well-nourished individuals. (2) However, the literature has stated that in patients with a nutritional deficiency or catabolic state restoring nutritional parameters might reduce the risk of infection.

LEVEL OF EVIDENCE: (1) Limited, (2) Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Evidence in the available literature demonstrates that malnutrition is a significant clinical and public health problem. Several clinical trials present NS as a global effort in medicine, with applications in different specialties to improve the general condition of patients

with malnutrition or metabolic stress secondary to trauma or infection and to modulate the inflammatory response and potentially mitigate negative outcomes. Although there are controversial results, in spite of several studies with evidence level I on both supporting and refuting this initiative [1–7]. The literature has shown certain indications for prescription of NS in surgery, most recently defined by the European Society for Clinical Nutrition and Metabolism (ESPEN) guideline in 2017 [2]. There are two published meta-analyses concerning the effect of perioperative oral NS on elderly patients after hip surgery. The first combined 10 randomized control trials (RCTs) involving 986 elderly patients, which showed that oral NS had a positive effect on the serum total protein ($p < 0.00001$) and led to a significantly decreased number of complications ($p = 0.0005$). Furthermore, data from the infection subgroups showed significant decreases in wound infection (odds ratio (OR) = 0.17; 95% confidence interval (CI): 0.04, 0.79; $p = 0.02$), respiratory infection (OR = 0.26; 95% CI: 0.07, 0.94; $p = 0.04$), and urinary tract infection (OR = 0.22; 95% CI: 0.05, 0.90; $p = 0.03$) [6]. The second pooled the results from 11 RCTs (multinutrient, oral, nasogastric and intravenous supplementation), with an NS group of 370 elderly people controlled with a group of 357 elderly, non-NS patients. This study demonstrated a reduction in complication rates (e.g., pressure sores, chest infection) at 1-12 months in the NS group (123/370 versus 157/ 367; relative risk (RR) 0.71; 95% CI 0.59 to 0.86) [7], but not on rates of surgical site infection (SSI). However, NS use in an elderly population with acute fractures remains controversial and the prescription is reserved for underfed or malnourished patients in an attempt to reduce complications during hospitalization [2,6]. According to the World Health Organization (WHO) and ESPEN, malnutrition is considered when a patient has a 10-15% weight loss within six months, 5% in three months and/or has a Body Mass Index (BMI) under 18.5 kg/m^2. There are hematologic parameters evaluated throughout the literature, such as a serum albumin/globulin ratio below 1.5 (normal range), albumin below 3.0 g/dl, lymphocyte count below 1,500 cells/mm^3 and a lymphocyte//monocyte ratio below five versus one that allows selective screening of suspected malnutrition [3,5,8–10]. This is a special topic of interest in patients with factures, due to the fact that approximately 50% of patients with orthopaedic infections had some degree of malnutrition and immunosuppression regardless of age [3].

Evidence favoring NS has revealed that supplementation containing protein could produce beneficial effects by reducing the risk of infection in patients with fractures and nutrition deficiencies, regardless of age [2,4,5,11]. In a 2012 clinical trial, Myint et al. describe significant differences in BMI comparing the supplementation arm versus a control group [4]. Also, NS also prevents weight loss during a prolonged hospital stay, improving the general state of the muscles and muscular strength, which could reduce hospitalization periods and thus lead to shorter exposure to nosocomial microorganisms [7,12]. Long et al. reported that patients with poor nutritional status and with infections lose a higher amount of protein during postoperative states through urine [13]. Furthermore, an altered nutritional status reflects a depleted physiological state that affects humoral and/or cellular immunity, limiting an effective response to infection [3]. These findings might explain why early enteral administration of NS reduces the risk of septic shock with an active infectious process [12]. NS also seems to prevent long periods of delirium, which in turn is associated with an increased mortality rate [14].

Despite the previous evidence, there is also available literature against the use of NS [7,12,15]. For instance, NS administration near the time of surgical intervention does not seem to have an important effect, as it cannot effectively change the traditional nutritional markers such as albumin or transferrin [8]. However, in a 2012 clinical trial, Gunnarsson et al. reported evidence of the utility of monitoring the insulin-like growth-factor 1 to evaluate the response of nutritional support in the short term [9].

Some studies report that NS should be used with caution, considering metabolic phenomena such as refeeding syndrome, a condition associated with quick NS in patients with severe malnutrition. In this case, a sudden increase in insulin stimulates hypophosphatemia and produces a decrease in the extracellular adenosine triphosphate (ATP) and two to three diphosphoglycerate on erythrocytes producing arrhythmia, respiratory failure and hematologic alterations. Prevention, monitoring and adequate dosage are key to the success of preventing such complication [16–18]. Standard nutritional supplements containing arginine, omega-3 fatty acid, glutamine and other components (immunonutrition) have level I evidence supporting its use in avoiding infection after colorectal resection [1].

Another meta-analysis (eight RCTs and two observational studies) showed that multiple nutrient-enhanced formulas demonstrate a benefit in reducing the risk of SSI compared to standard NS (very low-quality evidence) [19]. The population studied included adult patients undergoing major surgical procedures (mainly cancer and cardiac patients). Orthopaedic surgical procedures, however, were not included in this meta-analysis.

In conclusion, these results suggest that NS can have positive effects on avoiding wound infection and other infectious complications (respiratory infection, urinary tract infection) only in elderly patients after hip surgery. There are several limitations in the current literature with respect to recommending NS in acute fractures for every patient. It would be necessary to conduct further research to investigate the role of immunonutrition in orthopaedics, especially with respect to fractures.

QUESTION 3: Do preoperative pneumonia/urinary tract infections (UTIs)/trophic ulcers increase periprosthetic joint infection/surgical site infection (PJI/SSI) risk in femoral neck fracture patients treated by partial/total hip arthroplasty (THA)?

RECOMMENDATION: There is a paucity of literature examining whether pneumonia/UTI/trophic ulcers increase SSI/PJI risk for patients with femoral neck fractured treated by hemi- or THA.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 91%, Disagree: 0%, Abstain: 9% (Super Majority, Strong Consensus)

RATIONALE

Infection after femoral neck fracture treated with hemiarthroplasty/THA is an uncommon but devastating problem. The current literature cites a 1.7 to 7.3% risk of SSI after hemiarthroplasty for femoral neck fracture [1]. Commonly-cited risk factors for PJI/SSI after hemiarthroplasty for femoral neck fracture include higher Body Mass Index (BMI), prolonged surgery time, preoperative elevation in C-reactive protein (CRP) levels, surgeon experience level, reoperation and hematoma formation [2,3].

For patients undergoing primary total joint arthroplasty, pneumonia, UTIs and skin ulceration were shown to be predisposing factors for developing PJI [4–8]. However, there remains a lack of publications that specifically examine the risk of PJI/SSI related to the preoperative presence of pneumonia, UTI or skin ulceration in patients with femoral neck fracture treated with hemiarthroplasty or THA. One small prospective study demonstrated that UTI preoperatively was a significant risk factor for infection (odds ratio = 10; p = 0.04) [9]. A systematic review of the literature indicated that two or more urinary tract catheterizations during hospitalization was identified as a risk factor for SSI [1]. After a thorough investigation, we could not find any existing evidence of an association between preoperative pneumonia or trophic ulcers with the development of PJI/SSI after hemiarthroplasty or total hip replacement for femoral neck fractures.

In summary, there is scant or no evidence to suggest that preoperative pneumonia/UTI/trophic ulcers result in an increase in PJI/SSI risk in femoral neck fracture patients treated by partial/THA. The little evidence that is available is low quality and suggests that preoperative urinary tract infection increases the odds of PJI after hemiarthroplasty. Higher quality and larger scale studies are necessary in this subset population to make valid conclusions on this possible relationship.

QUESTION 4: Are there microorganism-specific risk factors for acute infection in trauma patients (i.e., does being a nasal carrier of methicillin-resistant *Staphylococcus aureus* (*S. aureus*), or MRSA, increase the risk for MRSA infection after trauma?)

RECOMMENDATION: The current evidence of an increased risk of infection is based on several risk factors, including MRSA colonization, presence of external fixator, anatomical location of surgery and severe open fractures. In these situations, alterations in antibiotic prophylaxis could be considered.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

MRSA colonization in the nares, axilla and other body sites has been associated with higher risk for MRSA surgical site infection (SSI) (cardiac and arthroplasties) [1]. Nasal topical decolonization, along with systemic antibiotic prophylaxis, has been shown to reduce the risk of MRSA prosthetic joint infections (PJIs) [2]. In a meta-analysis published by Schweizer et al. a bundle intervention consisting of nasal decolonization and glycopeptide prophylaxis showed a significant protective effect against MRSA PJI and cardiac surgical infection when all patients underwent decolonization (0.40, 0.29 to 0.55) and when only *S. aureus* carriers underwent decolonization (0.36, 0.22 to 0.57). Because only three randomized clinical trials (RCTs) assessed the risk associated with total joint arthroplasty, they also included seven studies assessing nasal decolonization for general orthopaedic surgeries. Most of decolonization regimens used mupirocin ointment into the anterior nares. In addition, seven studies assessed the bundle applied only for patients colonized with MRSA and found a significant protective effect against SSIs with gram-positive bacteria (0.41, 0.30 to 0.56) [3]. Therefore, there is a strong recommendation to perform nasal decolonization for those patients known to be at high risk for MRSA PJI.

However, nasal colonization with MRSA as an independent risk factor for MRSA infection after orthopaedic trauma and fractures has yet to be investigated. Taormina el al. prospectively assessed whether trauma patients with fracture nonunions who are colonized with nasal *S. aureus* (MRSA or methicillin-susceptible *S. aureus* (MSSA)) would be at greater risk of complications following surgeries, and if it would predict positive operative cultures. The study failed to demonstrate an association between MRSA or MSSA-colonized patients being treated for fracture nonunion of long bones with postoperative infectious complications. There was no significant difference in operative culture positivity or speciation between colonized or non-colonized patients [4]. On the other hand, in recent a non-randomized, 7-year prospective study in Japan, Nakamura et al. examined the role of preoperative nasal swabbing for *S. aureus* among patients who underwent several types of orthopaedic surgeries. One hundred and forty patients were MRSA nasal carriers (carriage rate 3.4%), even though only a minority of them (40) underwent osteosynthesis for fracture stabilization [5]. Nasal carriage of *S. aureus* or MRSA developed significantly more SSIs compared to non-carriers, suggesting that it may be a risk factor for SSI in orthopaedic surgery. Additionally, Croft at al. prospectively screened for MRSA colonization in 355 patients admitted to a trauma intensive care unit, of which 36 (10.1%) were colonized. Significantly higher rates of MRSA infection were diagnosed in the MRSA colonized group (33.3%) compared to those who were not (6.6%) ($p < 0.001$). Death rates were also higher among the colonized group compared to non-colonized patients, (22.2 vs. 5.% [$p < 0.001$]). Therefore, they recommended MRSA screening protocols at trauma units to identify these at-risk patients [6].

The current evidence that MRSA colonization predicts acute infection in trauma patients is scarce, but it suggests that assessment and decolonization may be beneficial in reducing fracture-fixation infection rates. Nixon et al. screened 1,122 trauma patients, of whom 3.8% were MRSA carriers, and after implementation of anti-MRSA policies the incidence of MRSA infection dropped by 56% [7]. The same group, in a retrospective study, identified 3.2% (79/2,473) MRSA carriage at admission in an acute trauma unit, and these patients were significantly more likely to develop MRSA SSI (7 of 79 patients, 8.8%) compared with 54/2,394 (2.3%) of MRSA-negative patients ($p < 0.001$). This difference was confirmed on multivariate analysis, in which the odds ratio for developing MRSA SSI among MRSA carriers was 2.5 ($p = 0.015$) [8].

Conversely, Kan et al. analyzed 66 patients with femoral neck fractures and rates of MRSA colonization and found no correlation between MRSA colonization and higher rates of postoperative infection. Nevertheless, this study presented several important limitations including the postoperative infection evaluation limited to the first immediate postoperative week and short follow-up evaluation no longer than four months [9].

Older patients with femoral neck fractures seem to be particularly prone to be colonized by MRSA. A large French retrospective multicenter cohort study identified an SSI rate of 5.6% in patients who had surgery for a proximal femur fracture, of which one-third involved MRSA. All infected patients received first-generation or second-generation cephalosporin for prophylaxis, whereas those who received antibiotics effective against MRSA (i.e., vancomycin or gentamicin) for prophylaxis had no MRSA SSI [10]. Similarly, a prospective cohort study assessed the MRSA colonization rates among patients with proximal femur fracture in a German trauma unit. Their conclusion and recommendation is to systematically search for MRSA colonization in patients presenting with known risk factors by swabbing them in the emergency room [11].

The role of MRSA carriage eradication among trauma patients admitted to the intensive care unit (ICU) as an independent measure to prevent MRSA infection was assessed in a large multi-center, patient-based RCT recently published by Maxwell et al. Those with positive nasal swabs were randomized to either daily chlorhexidine gluconate (CHG) baths and mupirocin (MUP) ointment to the nares or soap and water baths and placebo ointment (S + P) for five days. Upon admission, 13.3% (90/678) of patients were MRSA carriers, and clinical MRSA infection was significantly more often diagnosed in MRSA colonized patients (21.1%) than those who were not (5.4%, $p < 0.001$). Although underpowered to draw definitive conclusions regarding the role of MRSA decolonization with CHG + MUP to

reduce MRSA infection rates, due to the smaller number of recruited patients per treatment arm, the five-day treatment period resulted in only a trend towards the reduction of colonization, 13 (59.1%) vs. 9 (90%) for CHG + MUP vs. S + P (p = 0.114). There was no difference in the proportion of MRSA infections between CHG + MUP (seven [31.8%]) vs. S + P (six [60%], p = 0.244). CHG + MUP was ineffective in eradicating MRSA from the anterior nares, but may reduce the incidence of infection [12].

A pilot RCT evaluated SSI among patients with open fractures that received prophylaxis during 24 hours with cefazolin compared with vancomycin and cefazolin, depending upon their *S. aureus* colonization status. MSSA and MRSA carriers were 20% and 3%, respectively. Although underpowered with a sample size too small for a clinical efficacy analysis, no significant difference in the rates of SSI was observed between the treatment arms. A significantly higher rate of MRSA SSIs was observed among MRSA carriers compared with noncarriers (33% vs. 1%, respectively, p = 0.003) [13]. Other factors that raise the risk of MRSA infection include the use of external fixation and a prolonged time to intramedullary nailing of long bone fractures [14].

Torbert's retrospective study identified *S. aureus* and gram-negative rods (GNRs) as most commonly seen in deep postoperative infections. GNRs were seen more frequently in the pelvis acetabulum and proximal femur injuries even in closed fractures. Resistance to GNRs was lower than *S. aureus,* and the infection rates for combined surgical approaches were twice that of a single approach for acetabular or pelvic surgery [15].

Severity of open fracture plays a role in the choice of antibiotics. There was no statistically significant difference in infection rates between the group treated with ciprofloxacin and that treated with cefamandole/gentamicin for Types I and II open fracture wounds. A high failure rate for the ciprofloxacin only treated Type III open fracture group, with patients being 5.33 times more likely to become infected than those in the combination therapy group [16].

The anatomic location of surgery should be considered when administering preoperative antibiotics. Corynebacterium genera are frequently associated with implants when surgical incisions were made near the perineum [17]. *Cutibacterium acnes* is bacterial species that is often seen in the axilla and coverage for these organisms should be considered when operating near this anatomical location [18].

QUESTION 5: Is periprosthetic fracture a risk for the development of a periprosthetic joint infection (PJI)?

RECOMMENDATION: Infection rates from level III and IV evidence studies suggest an increased surgical site infection in patients who undergo re-operation for treatment of periprosthetic fracture of the femur after total hip and knee arthroplasty. There is limited literature available on periprosthetic acetabular and tibial fractures. Further study investigating the outcomes for treatment of periprosthetic fracture is recommended.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Periprosthetic fracture about a hip or knee replacement can be a devastating complication. Almost all studies involving periprosthetic fractures are limited to small, retrospective case series and many of the studies focus on one type of treatment for one type of fracture. Additionally, most of these studies focus on the return to function and union of the fracture as primary endpoints. As a result, there is limited data on the risk of surgical site infection in the presence of a periprosthetic fracture.

Periprosthetic fractures about the acetabular component of a total hip replacement are uncommon and typically involve high-energy injuries. Treatment is based on the fracture pattern and stability of the implant. Protected weightbearing or revision surgery, often with supplemental fixation, are utilized for treatment. A retrospective review of 11 patients did not discuss infection as a complication [1].

Periprosthetic fractures about the femoral component of a total hip replacement are most commonly reported in the literature. These fractures can be treated either nonoperatively or surgically, based on the fracture pattern and stability of the implant. Plate fixation, revision hip arthroplasty or combination treatment are the most common methods of surgical treatment. A study from the Swedish joint replacement registry identified 1,049 periprosthetic femur fractures treated surgically over a 21-year period. Over this period, 245 patients underwent re-operation, the most common reasons for failure being loosening, re-fracture and non-union. There was an infection rate of 2.3% (24 cases), and infection was more common in the plate fixation group than the revision hip arthroplasty group [2].

A study from the Mayo Clinic demonstrated 5 (4.2%) deep periprosthetic infections after femoral component revision of 118 Vancouver Type B periprosthetic fractures [3]. Similarly, a systematic review of 22 studies totaling 510 Vancouver Type B2 and B3 fractures demonstrated 13 (2.5%) surgical site infections [4]. In cases of extremely poor bone stock, a retrospective review demonstrated a 19% infection rate in 19 proximal femoral replacements [5].

Periprosthetic fractures about the distal femur after total knee replacement can be treated nonoperatively or surgically based on the fracture pattern and stability of the implant. Fractures can be treated with intra-medullary nail fixation, plate fixation or revision knee arthroplasty. A systematic review of 415 fractures from 29 case series demonstrated an infection rate of 3% [6].

Periprosthetic fractures about the tibia after total knee replacement are rare (0.4 to 1.7%) and can often be treated nonoperatively [7,8]. Surgical treatment with plate fixation, intramedullary nail fixation or revision arthroplasty is uncommon, and the current literature is limited to small retrospective case series.

While randomization would be difficult due to limited previous experience with these complicated cases, future study should involve prospective, multi-centered investigations involving larger numbers of patients to gain a better understanding of the natural history and outcomes of patients who undergo treatment for periprosthetic fractures.

QUESTION 6: Are there predictors of the need for allogeneic blood transfusion (ABT) in patients undergoing arthroplasty for acute hip fractures?

RECOMMENDATION: Preoperative predictors for the need for ABT include (1) anemia and (2) dementia and hypoalbuminemia. (3) Anticoagulation or anti-platelet medications do not predict the need for ABT. There is conflicting data with regard to the need for ABT when comparing hemiarthroplasty (HA) to total hip arthroplasty (THA).

LEVEL OF EVIDENCE: (1) Strong, (2) Limited, (3) Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Preoperative anemia is a known risk factor for ABT in patients undergoing hip and knee arthroplasty [1,2]. A retrospective study of 1,484 patients with hip fractures from 2007 to 2010 identified the risk factors for ABT as older age, lower hemoglobin on admission, female gender, type of surgical implant used (cephalomedullary nail and dynamic hip screw more than HA) and a shorter time from admission to surgery. The study is limited by transfusion thresholds, which may artificially increase the rate of ABT [3]. In hip fracture patients, regardless of fixation or fracture type, hypoalbuminemia [4] and dementia [5] are associated with an increased need for ABT.

Patients on chronic anticoagulation therapy are thought to be at risk for perioperative complications associated with bleeding. A level III retrospective study matched 62 patients with proximal femur fractures on warfarin with 62 patients not on anticoagulation therapy treated with an intramedullary nail, HA or THA. There was no significant difference in the rates of ABT in patients with international normalized ratio (INR) < 1.5 or with subgroup analysis of patients with an INR > 1.5 (range 1.5 to 3.1) [6]. There are three retrospective studies evaluating the preoperative use of clopidogrel in hip fracture patients with matched control patients comparing blood transfusion rates that report no significant increase in ABT [7–9].

A systematic review and meta-analysis of studies comparing surgical approaches and four studies comparing surgical approach for HA showed no difference in ABT rates between anterior, lateral and posterior approaches [10–13].

Perioperatively, medications such as hemocoagulase agkistrodon and tranexamic acid are administered to decrease blood loss. Multiple studies in the setting of femoral neck fracture have demonstrated a lower rate of ABT using these medications, but there remains a concern for increased risk of venous thromboembolism [14–17].

Much debate has centered on the treatment for displaced femoral neck fractures. Three prospective randomized controlled trials demonstrate no significant difference in the rate of ABT between cemented versus cementless femoral fixation in HA [18–20]. Multiple studies have reviewed differences between HA and THA for femoral neck fracture. Findings include longer operating times and increased blood loss in THA, but these studies can be difficult to interpret as patients undergoing THA are often younger and healthier [21,22]. Studies have demonstrated no difference in the rate of ABT [22,23], and increased rate of ABT in THA [21,24].

1.2. PREVENTION: RISK MITIGATION

Authors: Yousef Abuodeh, Per Åkesson, Osama Aldahamsheh

QUESTION 1: Is there a role for bacterial decolonization (i.e., of methicillin-resistant *Staphylococcus aureus* (*S. aureus*), or MRSA, in nares) in trauma cases?

RECOMMENDATION: It is unknown if bacterial decolonization in trauma patients reduces surgical site infection (SSI).

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

S. aureus colonization has been described since the early 1930s, and is linked to postoperative SSI in different surgical specialties, including orthopaedics. *S. aureus* resides in the nares, throat and skin surfaces in up to 30% of the population [1]. Establishing an association between bacterial carrier status and SSI in the setting of orthopaedic trauma has been challenging. The reported rate of MRSA carriers ranges from 1.8% up to 30% of hip and femur fracture patients [2–11], whereas the reported rates of MRSA-related SSI in those carrier populations ranges from 8.8% to 14.2% [6,12]. Furthermore, MRSA carriers displayed a higher incidence of other nosocomial infections and one-year mortality [4].

Although several published studies do support a connection between preoperative carrier status (for MRSA) with postoperative SSI development [13], it is uncertain whether it is due to the carrier status alone or due to other patient and disease factors [14]. One study refuted the need for widespread MRSA screening and eradication [15]. On the other hand, most literature has advocated addressing high-risk populations [6,9,16–18] for carrier status with prophylactic antibiotics against MRSA rather than decolonization preoperatively. Two main reasons have been postulated. First, one study found that in 86% of trauma cases in the setting of emergency fracture management, the results of MRSA screening would not be available before the surgical procedure commences [2]. Second, successful decolonization process will delay surgical procedures, which may not be ideal especially in hip fractures and open fractures.

With regard to decolonization, MRSA-related SSI was significantly reduced after decolonization protocol (without any reference to carrier status) from 2.3% to 0.33% [19]. However, one study demonstrated that MRSA screening and treatment policy reduced infection rates from 1.57% to 0.69% [5]. Furthermore, decolonization has been found to decrease total numbers of wound infection rather than wound infections caused by *S. aureus* [20].

For orthopaedic trauma cases, no prospective study of bacterial decolonization exists. The introduction of MRSA screening policies was evaluated in two retrospective studies including trauma patients [5,21]. Mupirocin was used for MRSA-positive patients, and both studies showed a significant reduction of postoperative MRSA infections. In a recent study on patients with lower extremity fractures, the addition of a povidone-iodine nasal swab in addition to a chlorhexidine-gluconate bath was evaluated [22]. Compared to two years before the start of the povidone-iodine intervention, the rate of SSI declined significantly.

Literature supporting decolonization in orthopaedic trauma patients only consists of low to moderate quality level 3 and 4 studies [19,20]. Literature not supporting decolonization consisted of one moderate quality level 1 study [23] and one low quality level 4 study [7]. As a result, a recommendation could not be made in favor of or against bacterial decolonization. Most importantly, screening should not delay surgical intervention in these patients, and these should be individually evaluated in a case by case scenario.

QUESTION 2: What are the ideal strategies to prevent secondary and nosocomial contamination of open fracture wounds which are left open?

RECOMMENDATION: Data support local antibiotics and early wound closure to reduce contamination of open facture wounds.

NOTE: The recommendation above was changed from the original version so the rationale below does not completely align with this recommendation. Please see Section 3:2, Question 2 for rationale for early wound closure. The rationale below regarding negative pressure wound therapy (NPWT) applies to Section 3:2, Question 4.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

METHODS

Randomized controlled trials, nonrandomized trials, prospective and retrospective observational studies were eligible for inclusion. We searched Medline, Embase, CINAHL, and the Cochrane Central Register of Controlled Trials (CENTRAL) up to March 2018 for published studies without language restriction. Our search strategy, including keywords and MeSH headings, are provided in the Appendix. Eligible studies met the following criteria: (1) all patients included in the study had an open fracture, (2) infection was an outcome variable and (3) there was a comparison between patients treated with a secondary infection prevention strategy and a control group or a comparison between two or more secondary infection prevention strategies.

RATIONALE

Some high-grade open fractures are left open and return to the operating room for one or more repeat debridement surgeries. Traditionally the wound was packed with a gauze dressing, which was changed between surgeries. There is interest in using different strategies to decrease surgical site infection (SSI), which is often thought to be caused by nosocomial pathogens. The two main current treatment strategies are the use of the NPWT (wound VAC) or antibiotic bead pouches.

A systematic review of the literature reveals four randomized trials with conflicting results investigating the practice of NPWT over simple gauze dressings between surgical debridement, and there are no randomized trials examining the efficacy of antibiotic bead pouches.

Until recently, the literature investigating the use of NPWT tended to show a reduction in infection rates with its use. However, this conclusion was contradicted recently by the WOLFF trial [1] which is a well-powered (n = 460) prospective trial on open fractures requiring multiple debridements. Patients were randomized to either standard dressings or NPWT. No effect on SSI was shown (7% in negative pressure vs. 8% in standard dressing, p = 0.64) [2].

Prior to the publication of the WOLFF trial, the literature had consistently favored NPWT but in smaller or lower-quality studies as summarized in a recently-published systematic review of the literature [3]. Three of the papers included in the review assessed the effect of NPWT on reducing SSI in open fractures [4–6]. There have been two additional randomized trials published more recently [7,8] and we identified two other retrospective studies on this topic [2,9]. Two of the three prior randomized trials demonstrated reduction in infection with NPWT (28% vs. 5%, p = 0.02, n = 62 [4] and 11% vs. 5%, p < 0.05, n = 93 [7]) and the third (n = 90) had a very low event rate and revealed no difference [8]. Three more retrospective studies showed similar results with relatively large reductions in infection rates with NPWT (55% vs. 19%, p = 0.04 [8], 21% vs. 8%, p = 0.01 [3], 33% vs. 10%, p = 0.03 [2]), and a fourth identified no difference despite a potential selection bias against NPWT due to higher-risk cases in that group [8].

Despite the widespread use of this technique in North America, there are few studies investigating the use of local antibiotic beads. These are composed of polymethal methacrylate (PMMA) cement mixed with antibiotics placed into the wound in a "bead pouch" that seals off the wound between debridement surgeries. One small pilot randomized trial investigated IV antibiotics versus antibiotic beads without intravenous (IV) antibiotics and found no difference in infection rates [10]. Three similar retrospective studies by one group [11–13] should probably be considered as one study, as all the

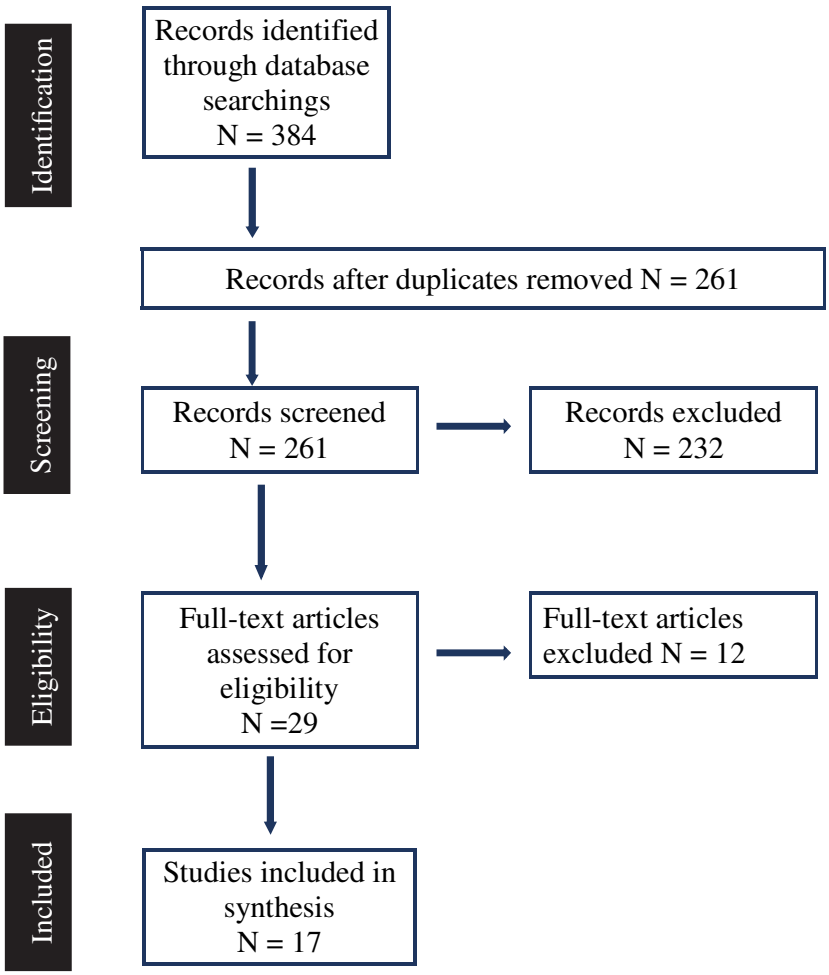

FIGURE 1. Flow diagram of study selection.

patients in one study appear to be included in the later study. This work demonstrated a significant reduction of infection rates (12% vs. 3.7%, p = 0.001) [12].

This said, one of the most important preventive measures seems to be the actual use of local antibiotics. A recent meta-analysis by Morgenstern et al., not included in this research strategy, suggests a risk reduction in infection of 11.9% if additional local antibiotics are given prophylactically for open limb fractures. Most studies in this review used PMMA beads as local carrier for the antibiotics [14]. Furthermore, support for the use of topical antibiotics in open wounds is from recent animal studies in rats [15–17] and goats [18] by a single research group using contaminated open fracture models.

QUESTION 3: Is there a difference in the risk of periprosthetic joint infection (PJI) with use of internal versus external fixation for treatment of periprosthetic fractures?

RECOMMENDATION: Unknown. There is limited evidence comparing the risk of PJI with use of internal versus external fixation to treat periprosthetic fracture. The potential for pin tract infection, particularly with inadvertently placed intra-articular pins, make internal fixation the preferable treatment option in most cases.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 90%, Disagree: 5%, Abstain: 5% (Super Majority, Strong Consensus)

RATIONALE

The majority of studies that have explored this question describe periprosthetic femur fractures after total knee arthroplasty (TKA). Periprosthetic femur fractures following TKA are an uncommon complication (0.3 to 2.5% incidence rate per year), but are occurring more frequently given the higher rate of primary TKA and increased activity of the elderly patients who are at the highest risk [1–3]. Treatment options currently include nonoperative management (protected weightbearing, bracing, casting), open reduction internal fixation (ORIF), or, rarely, external fixation [1,4]. Given the success of ORIF, there are few reports on the use of external fixation [1,2,4]. In addition, external fixation has historically been avoided given the belief that external fixation pins near a total joint increases the risk for superficial and deep infection [2].

Within this specific clinical setting, there is limited knowledge given the lack of large series of periprosthetic femur fractures treated with either internal or external fixation. The only reports of external fixation for these fractures are case reports. Based on the current literature, there is no difference in the rate of deep infection following internal fixation (rate = 4%) versus external fixation (rate = 7%, p = 0.8). This analysis is severely limited by the small sample size, so it is difficult to make any definitive statement regarding the differential risk for PJI after internal or external fixation of periprosthetic fractures.

ORIF is preferred given its high rates of union and low rates of infection (~ 3%) [1,2,4]. For patients who are too ill or are contra-indicated for ORIF, treatment options include nonoperative management or external fixation. While the infection rate for nonoperative treatment is predictably low (0 to 1%), 31% of patients had complications related to malunion or nonunion [2,3]. Given this poor outcome, some have turned to external fixation [3,5–9].

A recent systematic review found that the rate of deep infection/PJI following ORIF was 4.1% (10 out of 245 reported patients). Among all published reports using external fixation, the rate of superficial pin site infection was 28.6% (4 out of 14 reported patients) and the rate of deep infection/PJI was 7.1% (1 out of 14 reported patients) [3,5–9]. The rate of PJI between internal versus external fixation was not statistically significant (p = 0.8 by chi-square test). Based on this data, the risk of PJI is not statistically significantly different following internal or external fixation of periprosthetic femur fractures, but this analysis is severely limited by small sample size.

There are only two case series that report on use of external fixation to treat periprosthetic fractures. Assayag et al. successfully treated two periprosthetic tibia fractures using a circular external fixation frame without superficial or deep infection [10]. Interestingly, Sakai et al. successfully treated an infected periprosthetic total hip arthroplasty femoral fracture with Ilizarov external fixation with resolution of the infection [11].

There has been no systematic study of this topic. Thus, it is therefore challenging to make a definitive statement regarding any possible differential risk for PJI after internal or external fixation of periprosthetic fractures. Internal fixation appears to be the preferable treatment method with a trend toward lower risk of PJI, as well as the potential for improved alignment and function with better reduction and fixation.

QUESTION 4: Should definitive fixation of fracture in a polytrauma patient and open abdomen be delayed until the abdomen is closed?

RECOMMENDATION: Definitive fracture fixation in the presence of an open abdomen should not be delayed and could be performed safely if the patient is suitable to undergo surgery.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 95%, Disagree: 5%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Laparotomy is a well-established intervention in a polytrauma patient aimed to achieve rapid hemostasis and limit the contamination generated by intestinal, biliary or urinary leak [1–3]. However, abdomen closure cannot be carried out until edema has resolved to allow tension-free closure [1]. It is known that delayed abdominal closure after damage-control laparotomy reduces mortality, complications and length of stay. Nonetheless, definitive abdominal closure is not performed until the requirement for on-going resuscitation have ceased, no concerns regarding intestinal viability persist and no further surgical re-exploration is required [4]. Abdominal closure has been associated with fewer complications if performed within the the 4 to 7 days following laparotomy [4].

Early appropriate care of spine, pelvic ring, acetabulum and unstable femoral fractures in polytrauma patients decreases intensive care unit (ICU) length of stay from 9.4 to 4.5 days and total

hospital stay from 15.3 to 9.4 days [5]. However, definitive fracture fixation in patients with an open abdomen is often delayed due to the perceived increased risk of complications, specifically surgical site infection (SSI) [6].

One retrospective study has evaluated the safety of definitive fracture fixation in the presence of an open abdomen [6]. This study supports early definitive surgical management of spine, pelvic, acetabular and long bone fractures through minimally invasive techniques and standard open approaches. Time from injury to fixation surgery averaged 4.4 days when it was done in the presence of an open abdomen and 11.8 days when it was deferred until abdominal wall closure. The incidence of SSI that required surgical intervention was 3.1% in the first group and 30.6% in the second. No significant differences were found in terms of mortality, hospital length of stay or number of ventilator-dependent days.

Based on the limited available literature, there is no reason to delay definite fracture fixation in polytrauma patients with an open abdomen. Patients may benefit from early fracture fixation, not only from having reduced ICU and overall length of stay reduction, but infection risk reduction as well. We recommend that patients undergo definitive fracture fixation in the setting of an open abdomen if the patient is medically stable, does not have an active infection and is suitable to undergo surgery.

Diagnosis

Authors: Andres Pinzon, Kenneth Egol

QUESTION 1: Which open fracture classification system currently used (Gustilo-Anderson classification or the Orthopaedic Trauma Association's open fracture classification (OTA-OFC)) is preferred, based on interobserver reproducibility and predictiveness of outcomes?

RECOMMENDATION: OTA-OFC is preferred. Based on currently-available data, the OTA-OFC provides a more robust description of the injury with interobserver agreement that is comparable or superior to the Gustilo-Anderson classification. Additionally, the OTA-OFC, according to its subcategories, may predict outcomes such as the likelihood of early amputation and need for adjuvant treatments.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 95%, Disagree: 0%, Abstain: 5% (Unanimous, Strongest Consensus)

RATIONALE

The Gustilo-Anderson classification was introduced in 1976 for use in describing open fractures of the tibia [1,2]. Originally comprised of Types I through III, Type III was later subdivided into subtypes A through C to allow for the classification of "severe" fractures with greater specificity [2,3]. It has since been adopted for describing open fractures of all long bones and remains the most widely-used system for classifying open fractures [2].

The Gustilo-Anderson classification was found to have only moderate interobserver agreement when investigated by Horn et al. [4] and Brumbeck et al. [5], with an overall agreement of 66% and 60%, respectively. Clinically, the Gustilo-Anderson classification is well-established as a predictor of infection and amputation [1–3,6–8]. It provides a method of stratifying open fractures broadly into "mild" and "severe" categories.

The OTA-OFC was introduced in 2010 as a system for describing open fractures of all locations [9]. Rather than utilizing a single composite score, the OTA-OFC is comprised of five discrete components (skin, muscle, arterial, contamination and bone loss) each of which are independently rated mild, moderate or severe [9].

Studies suggest that inter-observer agreement throughout the OTA-OFC system is "moderate" to "good" overall [10,11], a statistic that is comparable or superior to that which has been reported for the Gustilo-Anderson classification [4,5,10]. This must be interpreted with caution, however, as the OTA-OFC is not aggregated and inter-observer agreement is not comparable among the five categories [10]. Studies assessing reliability have found that agreement is less robust within the muscle, bone loss, and contamination categories of OTA-OFC, suggesting that these categories may benefit from revision or clarification [10,11].

Initial studies in predictive utility of the OTA-OFC are promising. Agel et al. found different categories useful in predicting certain treatment modalities: the skin category for vacuum-assisted closure; bone loss category for antibiotic bead placement; skin and muscle categories for multiple debridements; and skin, contamination and arterial injury categories for early amputation [12]. Johnson et al. found it to be predictive of amputation and infection within 90 days [13]. Hao et al. found it to be predictive of amputation when the cumulative score was ≥ 10 [14].

While further studies validating the OTA-OFC are needed, the current literature suggests that it provides a method of describing open fractures with greater specificity compared to the Gustilo-Anderson classification with comparable inter-observer agreement.

QUESTION 2: What diagnostic criteria must be fulfilled to diagnose surgical site infection (SSI) or fracture related infection (FRI) in orthopaedic trauma (including external fixators)?

RECOMMENDATION: Diagnostic criteria proposed by the International Consensus Group on FRI (published in 2017) should be used to diagnose infection in fracture cases. In cases, more than four weeks from fracture, histological confirmation of > 5 neutrophils per high power field is confirmatory of infection.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 85%, Disagree: 5%, Abstain: 10% (Super Majority, Strong Consensus)

RATIONALE

Unlike periprosthetic joint infections (PJI) which have clearly-defined diagnostic criteria [1], infection associated with orthopaedic trauma procedures does not. Orthopaedic trauma has a higher rate of SSIs compared to other surgical specialties, yet it lacks an infection definition agreement [2–4]. This is likely due to the great variety and complexity of skeletal trauma and variability of surgical procedures. According to the initial Centers for Disease Control and Prevention (CDC) definition of SSI in trauma, this could occur up to one year following surgery [5]. However, in their last revision, this time period has been reduced to 90 days [6]. This poses a challenge for diagnosis, since infections related to orthopaedic trauma are often subclinical and some only display pain without any other signs or symptoms [5,7]. Furthermore, the CDC guidelines distinguish between superficial incisional, deep incisional and organ/space infections. Bonnevialle et al. already stated that the term "superficial infection" is at best arbitrary [8], and poses particularly challenging problems in infection associated with orthopaedic trauma. Finally, in orthopaedic trauma research, these terms (e.g., superficial and deep) are often used inaccurately or inappropriately, which makes comparison of literature difficult [9]. In the current clinical literature, numerous terms other than SSI are used with respect to infections associated with orthopedic trauma procedures (e.g., posttraumatic osteomyelitis, osteitis). Often, no distinction is made between the terms osteitis and osteomyelitis. Overall, these terms seem not useful as the main issue is the presence of bacteria at the fracture site and around the implant, rather than the semantics of the pathogenesis of the infection [9].

Orthopaedic trauma surgeons realized that the definition for PJI, criteria for osteomyelitis and the CDC guidelines could not be easily extrapolated to fracture cases, and, therefore, a definition had to be developed. This was recently confirmed by an international survey for registered AOTrauma users. In this survey, surgeons were asked about the need for a working definition, and 90% of more than 2,000 surgeons who responded suggested that a definition solely focusing on infection in orthopaedic trauma (i.e., fractures) was required [10]. Therefore, a special effort was made, with the support of multipele orginazations, to develop (AO Foundation and European Bone and Joint Infection Society (EBJIS)) [9] and update (AO Foundation, Orthopaedic Trauma Association (OTA), EBJIS and PRO-Implant Foundation) [11] a consensus definition. The consensus group designated infection related to orthopaedic trauma (i.e., fractures) as FRIs and established a definition based on two different kinds of diagnostic criteria: confirmatory (infection definitely present if a confirmatory criterion is met) or suggestive (features associated with infection and requiring further investigation) criteria (Table 1).

Without question this consensus definition should be validated by prospective data collection in order to gather evidence of its use in clinical studies and to prove that it can become a valuable tool in comparative research.

TABLE 1. Criteria to define FRI

Confirmatory Criteria	Suggestive Criteria
1. Fistula, sinus or wound breakdown.	1. Clinical signs: pain increasing over time, local redness, local swelling, increased local temperature or fever.
2. Purulent drainage or presence of pus.	2. Radiological and nuclear imaging signs
3. Phenotypically indistinguishable pathogens identified by culture from at least two separate deep tissue/implant specimens.	3. Pathogenic organism identified by culture from a single deep tissue/implant specimen.
4. Presence of more than five polymorphonuclear neutrophil per high power field, confirmed by histopathological examination [12].	4. Elevated serum inflammatory markers: ESR, WBC, CRP
	5. Persistent or increasing wound drainage.
	6. New-onset of joint effusion in fracture patients.

FRI, fracture-related infection; ESR, erythrocyte sedimentation rate; CRP, C-reactive protein; WBC, white blood cell

External Fixation

The infection rates reported with the use of external fixators are higher than with osteosynthesis with an incidence of infection of up to 71% [13]. However, there is also no clarity in regards to the diagnosis of SSI in external fixation. There are two classification systems, Checketts-Otterburn and Sims, neither of which have been validated [13,14]. The most commonly used is the Checketts-Otterburn schema, which describes clinical signs such as redness, discharge, pain, edema, radiological changes in the screw-bone interface and compromise in several levels [15].

In conclusion, there is a scarcity of scientific evidence regarding diagnostic criteria to define SSIs in orthopaedic trauma. The CDC published guidelines for SSIs, which distinguish between superficial incisional, deep incisional and organ/space infections, seem not suitable to define/diagnose infection in orthopaedic trauma patients. The recently published, and thereafter updated, international consensus definition seems an adequate replacement. This definition introduces, instead of SSI, the term FRI. Furthermore, two levels of certainty around the diagnostic features are defined. Criteria can be confirmatory (infection definitely present if a confirmatory criterion is met) or suggestive. This definition should be validated by prospective data in the future.

QUESTION 3: What diagnostic criteria define infected non-union of long bone?

RECOMMENDATION: The lack of scientific evidence precludes the development of diagnostic criteria that are solely based on sound evidence. The combination of the consensus definition of fracture-related infection (FRI) with a nonunion is a reasonable starting place, however definitions of nonunion vary and both the FRI definition and any proposed criteria for long bone nonunion will need scientific validation.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 86%, Disagree: 9%, Abstain: 5% (Super Majority, Strong Consensus)

RATIONALE

Introduction

FRI is a feared musculoskeletal complication and one of the most challenging in trauma surgery. Currently, estimating the impact of FRI has been hampered by the lack of a clear definition [1,2]. Interestingly, this issue was previously raised in an Arbeitsgemeinschaft Osteosynthesefragen/Association for the Study of Internal Fixation (AO/ASIF) scientific supplement publication by Arens et al. in 1996, wherein the authors stated in a combined clinical and experimental study on FRI, "It is astonishing that in all papers in which infection is mentioned, the term 'infection' is not defined" [3]. In fact, this was confirmed by a recent systematic review, which showed that only a minority of randomized controlled trials (2%) in fracture cares use any kind of standardized definition of FRI [4]. The lack of a clear definition of FRI mirrors the situation for prosthetic joint infection (PJI) identified many years ago [1–5]. The situation for PJI [6] and diabetic foot infection, for example [7], has improved with consensus definitions emerging in recent years. Orthopaedic trauma surgeons realized that neither the definition for PJI nor the Centers for Disease Control and Prevention (CDC) guidelines could be easily extrapolated to fracture cases and that a definition for FRI had to be developed.

This was recently confirmed by an international survey for registered AOTrauma users. In this survey, surgeons were asked about the need for a working definition of FRI and 90% of more than

2,000 surgeons who responded suggested that a definition of FRI is required [8]. Therefore, a special effort was made, with the support of the AO Foundation, to develop such a consensus definition. The process that was followed was comparable to the one described by Cats-Baril et al. for the new definition on PJI [9]. Finally, in 2016, a consensus meeting concerning this topic was held with an international expert panel. This resulted in the current consensus definition for FRI, which was recently published [10]. This resulted in the current consensus definition for FRI, which was recently published and adopted by the AO Foundation and the European Bone and Joint Infection Society (EBJIS).

Classifications

There are multiple classifications described in the literature that subdivide FRI into discrete groupings, such as acute and chronic infections, or early, delayed and late-onset infections [2,11–13]. The authors of the recently-published consensus definition stated that there should only be a single definition for FRI based on specific diagnostic criteria. Two primary reasons were proposed for this decision. First, a subdivision would make such a definition unnecessarily complex and difficult to use in daily practice. Second, although the available classifications are time-related, these time windows are not based on scientific evidence. This supports the view that they are poorly-defined for FRI (e.g., time since injury, or time since onset of symptoms) and somewhat arbitrary. All these concerns pose serious problems from a definition point of view [4]. The authors did agree that acute and chronic infections are different entities that may require different treatment strategies, however it should not affect the way clinicians define FRI [10].

Diagnostic Criteria

Recent systematic reviews, of which two are currently under submission, have been performed to analyze the value of specific diagnostic criteria for FRI. Below, three systematic reviews on diagnostic criteria are summarized.

Clinical Criteria

Studies specifically focusing on clinical criteria to diagnose FRI are currently scarce and validation studies are nonexistent. In two systematic reviews, clinical criteria used to define FRI were described. In a study by Metsemakers et al., the aim was to identify definitions used in the literature to describe infectious complications after internal fixation of fractures [4]. A total of 100 randomized control trials (RCTs) were identified in the search. Clinical signs used to diagnose FRI in the included studies were: purulent drainage (16 studies), wound dehiscence/breakdown (5 studies), rubor (redness) (5 studies), calor (warmth) (4 studies), tumor (swelling) (4 studies), unspecified signs (4 studies) and fever (3 studies). Other parameters that were used to diagnose FRI were positive cultures (15 studies), treatment with oral antibiotics (6 studies), need for surgical debridement (5 studies), need for implant removal (4 studies), radiological signs (2 studies) and C-reactive protein (CRP) levels (1 study). Most authors included purulent drainage or discharge and positive cultures as parameters for the diagnosis of FRI [4].

In an ongoing systematic review by Bezstarosti et al., the authors are aiming to provide an overview of the available diagnostic criteria, classifications, treatment protocols and patient-related outcome measures for surgically treated FRIs between 1990 and 2017. Clinical signs used in the 93 included studies were: purulent drainage or discharge (34 studies), pain (14 studies), tumor (swelling) (9 studies), calor (warmth) (8 studies), wound dehiscence/breakdown (7 studies), rubor (redness) (7 studies), fever (5 studies) and unspecified signs (46 studies). It seems that swelling, pain and redness are often seen as signs of FRI, however, they are subject to interpretation and are difficult to measure. "Purulent drainage" and "wound dehiscence/breakdown" on the other hand, seem more appropriate as hard endpoints in the diagnosis of FRI.

Serum Inflammatory Markers

In an ongoing systematic review by van den Kieboom and Bosch et. al, the diagnostic value of the serum inflammatory markers CRP, leukocyte count (LC) and erythrocyte sedimentation rate (ESR) in suspected FRI were assessed. A total of 8,280 articles were identified, of which 6 [14–19] were included in this review. CRP, reported in 6 studies, appeared to be the most useful serum inflammatory marker with a sensitivity ranging between 60.0 and 100% and specificity between 34.3 and 85.7%, which is in line with current clinical practice [20]. LC was reported in five studies. Sensitivity ranged from 22.9 to 72.6% and specificity from 73.5 to 85.7%. Five studies investigated ESR; sensitivity and specificity ranged from 37.1 to 100% and 59.0 to 85.0% respectively. For the meta-analysis, four CRP studies, four LC studies and three ESR studies could be pooled. Meta-analysis of pooled results demonstrated only limited diagnostic value of the individual markers. Four studies analyzed the value of combining markers and reported an increased diagnostic accuracy. However, these results should be interpreted with caution as this is based on limited data from heterogeneous studies. Indeed, the results of all serum markers vary greatly between studies. Another issue identified when analyzing these studies was that different measuring devices, lab protocols and/or thresholds were used across studies. The authors, therefore, concluded that the analyzed serum inflammatory markers (CRP, LC and ESR) appear to be unsuitable to rule out or diagnose FRI. When these markers are used in a diagnostic flow chart, they should be interpreted with caution [10]. Future research protocols using continuous serum inflammatory marker values and standardized lab protocols are required to assess their combined value in the diagnosis of FRI.

Tissue and Sonication Fluid Sampling

In an ongoing systematic review, Onsea et al. analyzed the available evidence on sonication of fluid sampling and tissue tests for the diagnosis of FRI. Out of 2,624 studies, ten [14,21–29] fulfilled the predefined inclusion criteria. Five studies [21–25] focused on sonication fluid culture, two on polymerase chain reaction (PCR) [14,26] and two on histopathology [27,28]. One additional histopathology study [29] was found after screening of reference lists. The review demonstrated that there is evidence that sonication fluid culture may be a useful adjunct to conventional tissue culture, but there is no strong evidence that it is superior or can replace tissue culture. Regarding molecular techniques and histopathology, the evidence is even less clear. Overall, studies had variable gold standard definition criteria for comparison and poorly-reported culture methods. By updating the review, one additional paper [30] was found that is currently in press. In this study by Morgenstern et al., including unhealed FRI cases more than four weeks from the occurrence of the fracture, a bimodal cut-off for the presence of polymorphonuclears (PMNs) provided encouraging results in reducing the number of cases in which the diagnosis was uncertain [29]. During a recent second consensus meeting (i.e. AO Foundation, OTA, EBJIS and PRO-Implant Foundation) it was decided that this cut-off for the presence of PMN's was included as a confirmatory sign for FRI.

Finally, in the systematic review by Onsea et al., the authors concluded it is imperative that lab protocols become standardized and that uniform diagnostic criteria, as recently published in a consensus definition, are implemented.

Imaging Modalities

In a recent systematic review by Govaert et al. [31], the recent literature (from 2000 to 2016) on imaging techniques for the diagnosis of post-traumatic osteomyelitis was analyzed. The literature search yielded 3,358 original records, of which 10 articles [32–41] were included. This review included seven studies on different nuclear imaging techniques, two studies on magnetic resonance imaging (MRI), one study on computed tomography (CT) with no studies identified regarding plain X-ray. The sensitivity for white blood cell (WBC) count or anti-granulocyte antibody (AGA) scintigraphy ranged between 50 and 100%, specificity ranged between 40 and 97%. For fluorodeoxyglucose positron emission tomography (FDG-PET), sensitivity and specificity ranged between 83 and 100% and between 51 and 100%, respectively.

WBC scintigraphy combined with hybrid imaging technique of single photon emission computed tomography combined with CT (SPECT/CT) was assessed by two studies. A higher diagnostic accuracy was reported in both studies that used this combination. Three studies investigated the combination of FDG-PET with PET-CT, which provided a significant increase in diagnostic accuracy. However, the studies that looked into these combinations provided only limited information. The authors concluded that, compared to other imaging techniques, either WBC or AGA scintigraphy combined with SPECT/CT and FDG-PET combined with CT demonstrates the highest diagnostic accuracy for the diagnosis of post-traumatic osteomyelitis when compared to other imaging techniques. It should, however, be taken into account that these results are based on a small number of studies and that imaging techniques and patient populations were heterogeneous across studies.

By updating the systematic review, two more studies from the past two years could be found. A study by Govaert et al. [42], aimed to establish the accuracy of 192 WBC scintigraphies for diagnosing FRIs, and investigate whether the duration of the time interval between surgery and WBC scintigraphy influences its accuracy. The authors concluded that WBC scintigraphy had a diagnostic accuracy of 92% for the detection of FRI in the peripheral skeleton. The duration of the interval between surgery and the WBC scintigraphy did not influence its diagnostic accuracy. The second study, by van Vliet et al. [43], evaluated the efficacy and diagnostic accuracy of a semi-quantitative measure, maximum standard uptake value (SUVmax), for the interpretation of FDG-PET/CT in the differentiation between aseptic and septic delayed union of the lower extremity. A total of 30 patients were included: 13 patients with aseptic delayed unions and 17 patients with septic delayed unions. Mean SUVmax in aseptic delayed union patients was 3.23 (SD ± 1.21). Mean SUVmax in septic delayed union patients was 4.77 (SD ± 1.87). A cut-off SUVmax set at 4.0 showed a diagnostic accuracy of 70% to differentiate between aseptic and septic delayed union. The authors concluded that the application of SUVmax for the interpretation of FDG-PET/CT imaging seems to be a promising tool for the discrimination between aseptic and septic delayed union. However, as this is based on a small number of patients, they acknowledge that larger, prospective trials are necessary to make a further statement regarding the role of FDG-PET/CT in the diagnosis of FRI.

Due to the current lack of high-quality evidence on the value of imaging techniques, which is similar to the other diagnostic criteria discussed above, imaging techniques seem not suitable to rule out or diagnose FRI and can only be considered a suggestive sign [10]. This was also included in the recently updated (i.e. AO Foundation, OTA, EBJIS and PRO-Implant Foundation) international consensus definition of FRI.

The definition for non-union is currently not standardized, which makes it difficult to introduce diagnostic criteria for infected non-union. This said, overall there is little scientific evidence regarding the diagnostic criteria for FRI. With respect to serum inflammatory markers, tissue, sonication fluid sampling and imaging modalities, only a small number of studies are available. Validation studies on clinical parameters are nonexistent. This lack of scientific evidence precludes the development of diagnostic criteria that are solely based on sound evidence. Moreover, it seems that developing diagnostic criteria for *both* acute/early infections and chronic/late (e.g., infected nonunion) infections is arbitrary and complicates clinical decision-making. Finally, although the scientific evidence on diagnostic criteria to define FRI is scarce, the international Consensus definition of FRI that was recently updated seems an adequate start and offers clinicians the opportunity to standardize clinical reports and improve the quality of published literature. In our opinion, this definition should be validated by prospective data collection in the future.

QUESTION 4: What differentiates acute from chronic osteomyelitis (OM)? Is it clinically important to distinguish one from the other?

RECOMMENDATION: Current literature is lacking consistent criteria for a distinct time point that differentiates the acute and chronic forms of infection. Differentiating between acute and chronic types may have practical implications on treatment plan and final prognosis.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 95%, Disagree: 5%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

To address this question an extensive search of the literature was conducted. Our search aim was to identify articles reporting on the diagnostic criteria for acute or chronic osteomyelitis. A clear definition of OM in terms of temporal evolution was considered mandatory. Furthermore, in order to investigate the potential practical significance of the temporal distinction of OM into acute or chronic types, we aimed to identify papers reporting on the outcome of antimicrobial therapy or combined treatment (antimicrobial plus surgical intervention) of acute osteomyelitis. Our exclusion criteria included case reports, expert opinions, experimental studies, infections associated with prosthetic implants, diabetic ulcers and non-orthopaedic bone infections (facial, cranium, ribs).

We searched the Medline, Embase, Ovid, Cochrane and Google Scholar databases using the PubMed search engine. Our search strategy included the following Medical Subject Headings (MeSH) terms and Boolean operators: ("osteomyelitis"[MeSH Terms] OR

"osteomyelitis"[All Fields]) OR "bone infection"[All Fields] OR "osseous infection"[All Fields] AND ("classification"[Subheading] OR "classification"[All Fields] OR "classification"[MeSH Terms]). This search process yielded 856 records. After rejection of duplicates and irrelevant articles by their title or abstract, there remained 45 papers for which full text was obtained. After careful screening against the eligibility criteria, there were ultimately eight eligible articles left.

A second search process was run in parallel, as follows: acute [All Fields] AND ("osteomyelitis"[MeSH Terms] OR "osteomyelitis"[All Fields]) AND "humans"[MeSH Terms]. It yielded 3,339 results. After removal of duplicates and rejection of irrelevant articles based on their title or abstract, there were 56 studies remaining, for which a full text was obtained. Eventually, after screening of these manuscripts against the eligibility criteria, another 11 eligible articles were obtained. In addition, another 4 articles were added from handsearch of the relevant bibliographies, leading to a total of 23 eligible articles (see Fig. 1).

OM is an inflammation of the bone and bone marrow caused commonly by pyogenic bacteria, and rather infrequently by mycobacteria or fungi [1,2]. It is classically classified by the duration of its clinical course as acute or chronic. Acute osteomyelitis represents the early stage of the evolutionary process of the disease, usually characterized by an intense clinical picture. Its diagnosis is based on a combination of clinical, laboratory and imaging findings, with a definitive diagnosis established by positive bacterial cultures of aspirate, bone or blood samples [3]. A longstanding infection which progresses to bone necrosis and sequestrum formation is termed chronic OM [1,2,4]. This condition is usually characterized by more subtle clinical findings, occasionally the presence of draining sinus tracts, or may progress intermittently [5]. While the clinical differentiation is marked by necrosis and sequestrum formation, defining a specific time threshold beyond which an acute infection could be considered chronic is difficult [1,2]. The current literature is lacking consistent criteria for a distinct time point that differentiates the acute and chronic forms of infection. Nevertheless, this distinction is of only limited value in adults as they are very rarely affected by acute OM and, even if this does occur, prompt diagnosis before transition to chronicity is often missed. On the contrary, in children, who are frequently affected by acute hematogenous OM, differentiating between acute and chronic types has practical implications regarding the treatment plan and final prognosis. This is mainly due to the fact that younger patients have the ability to resorb, at least to some degree, devitalized bone tissue, thereby removing foci of "biofilm type" of bacterial growth and potentiating the effectiveness of early-instituted antimicrobial treatment [6]. Additionally, the duration of this antimicrobial treatment differs between acute and chronic OM, with the acute form being treated with three to six weeks of specific antimicrobials targeted at identified pathogens after initial empiric formulations, and the chronic form being treated for up to six months with targeted antimicrobial therapy without initial empiric therapy [7]. This is due to the fact that certain pathophysiological changes that occur during the evolution of the inflammatory process (such as pus formation, reparative reaction, formation of involucrum and bone sequestration), which dictate the treatment plan and prognosis, are time-dependent [8]. Consequently, the differentiation between an acute and chronic form, especially in children, has important implications on the treatment plan.

Some authors do not utilize strict temporal criteria for defining OM. In 1970, Waldvogel et al. emphasized the difficulty in distinguishing between acute and chronic OM in terms of clinical course (type and duration of symptoms) or histologic findings [9,10]. They classified all cases as either "initial episodes" or "recurrences." An initial episode was thought of as representing an acute type of the disease spectrum, while recurrences represented chronic cases. They documented significantly higher treatment failures in "recurrences" as compared to the "initial episodes" for both hematogenous cases ($p = 0.003$) and those secondary to a contiguous focus of infection ($p = 0.0005$). The same definition of acute OM as "initial episode" was adopted by Lieu et al. in a retrospective study of 95 patients aged less than 17 years [11]. Fifty-five percent of them had been treated conservatively, while the remaining 45% had received combined treatment (antimicrobial therapy plus surgery). A recurrence rate of only 8.5% was documented. Other authors utilized a list of clinical, laboratory and imaging criteria to define acute OM in children and adolescents [12–14].

Various temporal thresholds have been used to define acute OM (Fig. 1). The shortest time threshold was one week, and was documented in three studies reporting on pediatric populations (584 children) [15–18]. The percentage of surgical intervention across all three studies ranged from 5.3% to 56%, and the recurrence rate of the infection ranged from 0 to 12% (pooled estimate of effect size for recurrence rate [random effects model]: 3.5%, 95% confidence interval (CI): 0.1 to 11.5%, with significant statistical heterogeneity: $I^2 = 87\%$). In one study, a sub classification of acute hematogenous OM was proposed into early-acute OM (diagnosed within 48 hours of onset in children over one year of age), late-acute OM (diagnosed at 5 days or more in children over 1 year of age) and neonate-infantile type [16]. The rationale for this classification was based on the findings of the study that the success rate of antimicrobial treatment was 92% for early-acute type versus 25% for late-acute OM. Another commonly-used threshold was two weeks and was utilized by studies reporting on either pediatric [19–21], adult [22] or mixed populations [23]. Two out of the three studies dealing with the pediatric population reported on the recurrence of the acute infection, which ranged from 0 to 7% (pooled estimate of effect size [random effects model]: 3.6%, 95% CI: 0.02 to 13%, $I^2 = 79\%$), with the rate of operative intervention ranging from 8 to 44% [19,20]. Finally, in one study reporting on open, infected bone wounds of the distal fibula/tibia, an acute infection was considered when the duration of open wound drainage was less than six weeks [24].

The definition of chronic OM is much more variable in the literature. Various lower limits of duration of symptoms exist, above which a chronic osseous infection is considered (Figs. 2 and 3). These range from at least a week in one study [17] to at least six months in three studies [25–27]. In-between, there are studies using the lower limits of two weeks [23], six weeks [24], one month [22] and two months [28]. However, in all studies the most consistent sign of chronicity of infection was bone sequestration. In a recent systematic review of the literature on the classification on the long bone OM the authors concluded that the terms acute/chronic OM are unreliable and do not influence the diagnostic workup or the principles of medical or surgical management [29].

Given the great variability of definitions for acute and chronic OM existing in the literature, we conclude that these terms are impractical in most cases as they lack accuracy in describing the underlying disease, and cannot dictate the treatment plan or predict prognosis. An exception to the above conclusion is the pediatric cases of acute OM due to the greater capacity of the younger patients to absorb necrotic bone and, therefore, to potentiate the effects of medical treatment. Additional variation in the treatment plan between acute and chronic forms of OM is in the duration of antimicrobial treatment. Lima et al. concluded that in acute cases patients should be given initial empiric antimicrobial treatment followed by targeted treatment for three to six weeks, while chronic cases require up to six months of targeted therapy [7].

QUESTION 5: Is synovial fluid or fracture hematoma always aseptic? If not, could this play a role in acute infection or periprosthetic joint infection (PJI) after open reduction and internal fixation (ORIF)?

RECOMMENDATION: Fracture hematoma is not always aseptic. It is unknown if synovial fluid is always aseptic. In addition, it is unclear if this plays a role in acute infection or fracture-related infection (FRI) after ORIF.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 95%, Disagree: 5%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

The association between soft-tissue conditions and infection has been well-known since the 1970s, when Gustilo and Anderson described how the major risk factor for post-traumatic infection following open fracture was the quality of the soft tissue envelope [1]. More recent evidence has demonstrated how traumatized host tissue can result in altered vascularization, decreased perfusion, increased endothelial permeability and decreased oxygenation; all of which can compromise the body's innate ability to resist local infection [1,2]. The prevailing theory of infection is that it is secondary to inoculation of pathologic microorganisms in traumatized tissues; however, it is unclear how infection occurs in closed trauma if there is no bacterial contamination through an open wound [2]. Some have questioned the common belief that synovial fluid and fracture hematoma is always aseptic based on evidence from other surgical fields that demonstrated how bacterial balance within presumably clean soft tissues affects the likelihood of soft tissue healing versus infection [3].

Two recent studies explored if fracture hematoma or callus was aseptic. In contrast to the prevailing view that these tissues are always clean, both studies found that 14 to 40% of the deep tissues grew bacteria when cultured, but no study has replicated these findings with synovial fluid. Szczesny et al. used conventional and molecular bacterial detection methods to determine if bacteria colonized lower limb soft tissues and bone following closed fractures in 71 patients. Cultures of fracture callus were positive in 26.7% of patients and bacterial rRNA was isolated in 41% of patients [4]. Similarly, Font-Vizcarra et al. evaluated the presence of positive cultures from hematoma in 109 patients with femoral neck fractures. They found that fracture hematoma was positive in 31.2% of all patients [2]. In both studies, the most common cultured organism was *S. epidermidis*. Based on recent basic science data, the presumed mechanism of infection of the deep tissues was that high-stress conditions resulted in decreased ability to contain skin and mucosal flora, leading to seeding of traumatized soft tissues/hematoma by lymphatic spread or transient bacteremia [1,2,4].

Although there is good evidence that fracture hematoma is not always aseptic, it remains unclear if the bacteria within the deep tissues play a role in acute infection or PJI after ORIF. Font-Vizcarra et al. did not find that culture positivity was a risk factor for early post-traumatic infection unless the specimen grew gram-negative rods [2]. Similarly, positive cultures from the fracture callus was not associated with non-union following closed tibia or femur fractures

[4]. Based on this data, it is unknown what bacterial load is necessary to evoke infection and overwhelm the host response [3].

QUESTION 6: What is the relationship between implanted metal and colonization under a vacuum-assisted closure (VAC) in open fractures?

RECOMMENDATION: The use of negative pressure wound therapy (NPWT or VAC) over exposed orthopaedic implants has been reported but its role remains unknown. Furthermore, no evidence exists regarding the effect of NPWT on the colonization of metal implants in open fractures. Further research is required to provide more insight into this question.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

NPWT has emerged as a promising modality for the treatment of open fracture wounds between operative debridements and delayed wound closure or coverage [1,2]. Traditional management of fractures with soft tissue defects included wet-to-dry dressings with the risk of wound contamination and infection rates reportedly as high as 50% [3]. In addition to providing a semiocclusive dressing, NPWT mechanisms of action include stabilization of the wound environment, reduction of wound edema, improvement of tissue perfusion and stimulation of cells at the wound surface [1]. While initial randomized controlled trials (RCTs) favored NPWT in reducing infection in open fractures [4], a recent Cochrane database review found little difference compared to standard dressings [5]. The ability to successfully clear the infection may be tied to the VAC's effect on the wound bioburden [6].

A recent systematic review identified 24 studies investigating the topic of bacterial growth and NPWT, but none contained exposed implants [6]. The authors identified 10 experimental studies, 4 RCTs, 6 clinical studies and 4 using an instillation VAC system [6]. Of the RCTs, only one quantified bacterial proliferation and performed species analysis. Moues et al. found that NPWT selectively reduced non-fermentative gram-negative bacilli (NFGNB) but increased the proliferation of *S. aureus* [7]. The other three RCTs found no difference with the NPWT in regard to reduced bacterial growth or number of positive cultures [6]. The authors of this review concluded that there was a lack of concensus in the literature if the NPWT increases, decreases, or has no effect on the wound bioburden.

Perhaps even less is known about the relationship between implanted metal and colonization under a NPWT device in open fractures, as no studies have investigated this topic. The main reason is that contemporary "fix and flap" open fracture treatment does not advocate the use of NPWT devices over exposed metal. Some cases where this treatment might be an option include: (a) open fracture treated initially with hardware that undergoes wound breakdown, (b) if hardware removal at debridement is not feasible or would drastically compromise limb stability or (c) the patient is not a medical candidate for additional soft tissue coverage or additional surgery [8]. In such cases, the recommendation is to perform a secondary early coverage with local or distant flaps, but NPWT is not an option for definitive treatment. While case reports and small series have described the use of a wound VAC over exposed orthopaedic hardware in other instances [8–13], no studies have included bacterial proliferation or speciation analysis.

In conclusion, while there is evidence supporting the safety and efficacy of NPWT over exposed metal for a period of time without infectious complications, there are no published studies investigating this in associaton with open fractures. While the use of NPWT in open fractures with exposed metal is a viable option, it is not a part of the contemporary treatment of open fractures. Further research and study into implant colonization under a NPWT will be required before such a practice can be routinely recommended.

Treatment

3.1. TREATMENT: ANTIBIOTICS AND NONOPERATIVE MANAGEMENT

Authors: Willem-Jan Metsemakers, Charalampos Zalavras

QUESTION 1: What is the most optimal prophylaxtic antibiotic coverage and treatment duration for open fractures of long bones?

RECOMMENDATION: The use of prophylactic antibiotics for open fractures of long bones has a protective effect against early infection. Antibiotics should be administered as soon as possible after the injury. The antibiotic of choice should target gram-positive organisms. Additional coverage for gram-negative organisms should be considered for patients with high-energy open fractures. Antibiotics should not be continued for more than 72 hours after wound closure.

LEVEL OF EVIDENCE:

- Efficacy of prophylactic antibiotics – Strong
- Timing of prophylactic antibiotics – Moderate
- Choice of antibiotics – Limited
- Treatment duration – Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Efficacy

Antibiotic administration has been shown to decrease the infection rate in open fractures in randomized controlled trials [1,2] as well as systematic reviews [3,4]. Patzakis et al. demonstrated for the first time the benefit of antibiotics in a prospective, randomized study [1], in which the infection rates for cephalothin versus penicillin with streptomycin versus no antibiotics were 2.3%, 9.7%, and 13.9%, respectively. In a Cochrane review data from 1,106 participants in eight studies were analyzed. The use of antibiotics had a protective effect against early infection compared with no antibiotics or placebo (risk ratio (RR) 0.43, 95% confidence interval (CI) 0.29 to 0.65, absolute risk reduction 0.07 [95% CI 0.03 to 0.10]). [3]. Another more recent systematic review also suggested a large, consistent reduction in infection risk with antibiotic use (RR 0.37, 95% CI, 0.21 to 0.66) [4].

Timing

In a retrospective study of type III open tibial fractures by Lack et al., administration of systemic antibiotics more than 66 minutes after injury was significantly and independently associated with deep infection (odds ratio (OR), 3.78, 95% CI, 1.16 to 12.31) [5].

Based on the quality and quantity of available evidence, the initial strength of the recommendation for early administration of antibiotics would be limited. However, we can upgrade this recommendation to one of moderate strength based on the following factors: (a) there is strong evidence that antibiotics need to be given and (b) delaying the necessary administration of antibiotics does not convey any benefit that could balance the potential risk of increased infection rate with delayed administration.

Choice of Antibiotics

Target organisms for prophylactic administration should be contaminants in the wound. Studies evaluating the microbiology of open fracture wounds have consistently shown that most contaminants are gram-positive organisms [6,7]. A study of 616 type I and II open fractures of the tibia reported that bacterial contamination at the fracture site consisted of a similar distribution of gram-positive (75 to 78%) and gram-negative (22 to 26%) species upon arrival at the emergency department, at the start of the operation, and at wound closure [6]. Methicillin-resistant *Staphylococcus aureus* (MRSA) were absent among the strains isolated at these stages [6].

The importance of antibiotics covering gram-positive organisms (usually a first-generation cephalosporin) is widely agreed upon. However, the necessity of coverage against gram-negative organisms or against anaerobes remains controversial.

No studies in the literature have directly compared gram-positive coverage to combined gram-positive and gram-negative coverage. Patzakis et al. recommended addition of aminoglycosides in all open fractures and reported a reduction in the infection rate from 14.6% in open tibias treated with a cephalosporin (from 1976 to 1977) to 4.5% in open tibias treated with both a cephalosporin and an aminoglycoside (1979 to 1980). However, this was not a direct comparison but instead a comparison of patients treated in different time periods in two prospective studies [8]. Gustilo et al. reported that 77% of cultures isolated from infected open fractures were of gram-negative bacteria and advocated addition of aminoglycosides for type III open fractures [9]. Similarly, Vasenius et al. in a randomized controlled trial of clindamycin vs. cloxacillin reported high surgical site infection (SSI) rates in type III open fractures and advocated addition of an aminoglycoside in these severe open tibia fractures [10].

Contamination of open fracture wounds with gram-negative organisms, although less frequent, still occurs [6,7] and a severe open fracture may be misclassified due to limitations in the interobserver agreement of the Gustilo-Anderson classification [11]. However, the SSI rates of Gustilo type I and II fractures have been consistently low in the literature even with narrow-spectrum antibiotics that mainly target gram-positive species [9].

Therefore, administration of a first-generation cephalosporin is recommended for Gustilo I and II fractures [12–14] and additional administration of an antibiotic with good gram-negative coverage is recommended in Gustilo type III (e.g., aminoglycoside or 3rd generation cephalosporins) [13,14,15,16]. Aminoglycosides may cause nephrotoxicity, especially in the setting of renal disease or dysfunction; therefore, renal function should be considered beforehand. Pannell et al. reported that gentamicin use during treatment of open fractures does not lead to increased rates of renal dysfunction when used in patients with normal baseline renal function [17]. Unfortunately, renal function is often not known at the time of initial admission of antibiotics.

Anaerobic coverage (e.g., penicillin, clindamycin or metronidazole) is recommended in the presence of potential clostridial contamination (e.g., fecal contamination or farm-related injuries) [13,14]. However, no study has compared anaerobic coverage in such injuries. A group developing guidelines for combat injuries that are severely injured and contaminated did not recommend anerobic coverage, but instead emphasized early and thorough debridement.

The emergence of antimicrobial resistance in bacteria has created concerns about the adequacy of current antibiotic protocols, especially against MRSA. However, a randomized controlled trial comparing vancomycin and cefazolin versus only cefazolin in 101 patients with open fractures found no difference in the infection rates between the groups: 19% in the group receiving vancomycin and cefazolin versus 15% in the cefazolin only group [18]. As a result, the routine use of vancomycin in open fractures cannot be recommended based on available data.

Duration

Two randomized controlled trials compared one to five days of antibiotics in the management of open fractures [6,19]. Both studies reported that the infection rates were similar in the one-day and the five-day groups and advocated against the prophylactic administration of antibiotics for five days. However, no randomized controlled studies have compared one-day, two-day, or three-day antibiotic prophylaxis. A retrospective case control study of 1,492 open fractures by Dunkel et al. showed after multivariate analysis that there was no significant difference in infection risk for one-day prophylaxis compared with longer regimens [20]. Although the OR for infection in the two/three-day group compared to the one-day group was 0.6 (95% CI, 0.2 to 2.0) in all fractures and 0.3 (95% CI, 0.1 to 3.3) in type III fractures. These lower ORs were not found to be significant.

Prolonged prophylactic administration of antibiotics beyond 72 hours is not recommended. In the absence of additional data for type I and II open fractures we would recommend administration of antibiotics for at least 24 hours after wound closure, but not to exceed 72 hours. In type III fractures we recommend 72 hours of antibiotic administration or 24 hours after closure or soft tissue coverage of the wound, in agreement with existing guidelines [13,15,16,21].

QUESTION 2: What antibiotic(s) should be used for low-energy open fractures? What antibiotic(s) should be used for high-energy open and grossly-contaminated fractures?

RECOMMENDATION:

1. Antibiotic treatment targeting gram-positive organisms is recommended as soon as possible for all open fractures; low- and high-energy.
2. In high-energy or grossly-contaminated open fractures, additional antibiotics should be considered for gram-negative coverage.

LEVEL OF EVIDENCE: 1. Strong; 2. Limited

DELEGATE VOTE: Agree: 95%, Disagree: 0%, Abstain: 5% (Unanimous, Strongest Consensus)

RATIONALE

Open fractures are those that occur with associated skin and overlying soft tissue disruption, resulting in communication between the fracture site and the external environment [1]. The amount of energy imparted to an extremity during trauma results in a greater or lesser degree of bone and soft tissue compromise. Many authors have attempted to use different classifications to correlate the degree or amount of energy and the tissue compromise. The most commonly used is one described by Anderson et al. [2], later modified by Gustilo et al. [3]. For the purpose of this document, this definition will be used and correlated with the degree of energy associated. According to this classification, type I fractures are characterized by a wound of < 1 cm with minimal contamination, comminution and soft-tissue damage (these are low-energy). Type II features lacerations of > 1 cm and moderate soft- tissue injury, but wound coverage is adequate and periosteal stripping is not extensive (moderate energy). Type III fractures are divided into three subtypes and are all considered as high-energy. Type IIIA is characterized by high-energy trauma, extensive soft-tissue damage and substantial contamination, but wound coverage remains adequate after debridement has been completed. Type IIIB displays inadequate wound coverage following debridement and coverage procedures are required. Type IIIC is an open fracture associated with an arterial injury requiring repair.

One of the main purposes of this classification, besides description, is the correlation with infection rates which have been shown to increase correspondingly [4]. Rates of infection have been reported to range from 0% to 2% for type I, 2% to 5% for type II, 5% to 10% for type IIIA, 10% to 50% for type IIIB, and 25% to 60% for type IIIC3 [2,3,5]. Prophylactic antibiotics have become a standard for open fractures since 1974 when Patzakis et al. [6] demonstrated in his prospective study that cephalothin had significantly lowered the infection rate to 2.3 % compared with 13.9% in the control group. This finding was later confirmed by a systematic review demonstrating that the use of antibiotics had a protective effect against early infection compared with no antibiotics or placebo [7].

The efficacy of first-generation cephalosporins for open fractures has been confirmed in level I and II studies [7,8]. As initially reported by Gustilo et al. [3], type III fractures had a high rate of gram-negative infections, which supports the addition of an aminoglycoside or a third-generation cephalosporin. A different, prospective randomized study of severe open tibia fractures (type II and III) comparing first-generation cephalosporin and third-generation cephalosporin showed no statistical difference in the rate of infection [9]. *The Surgical Infection Society Guideline: Prophylactic Antibiotic Use in Open Fractures: an Evidence-Based Guideline* recommends the administration of first-generation cephalosporin for 24-48 hours preoperatively as a safe and effective prophylactic choice in patients with type I open fractures [10]. The *East Practice Management Guidelines Work Group: Update to Practice Management Guidelines for Prophylactic Antibiotic Use in Open Fractures* recommends that preoperative antibiotic prophylaxis for coverage of gram-positive organisms should begin for patients with open fractures as soon as possible after injury [11]. For type III fractures, additional coverage for gram-negative organisms may be given as these fractures are considered highly contaminated, although this aspect is not yet clearly supported by high-level studies [12].

QUESTION 3: What is the optimal mechanism for delivery of local antibiotics in contaminated or infected wounds?

RECOMMENDATION: There is moderate evidence to support the use of local antibiotic delivery in contaminated or infected wounds. Future data collection seems important to improve our knowledge on this topic.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 75%, Disagree: 15%, Abstain: 10% (Super Majority, Strong Consensus)

RATIONALE

The evidence regarding the optimal mechanism for delivery of local antibiotics in contaminated or infected wounds is moderate. Open limb fractures are often associated with considerable bone damage including periosteal stripping, extensive soft-tissue trauma and severe contamination [1,2]. This enables bacteria to establish a fracture-related infection (FRI) by breaching the damaged skin barrier and adhering to non-living surfaces, such as implants or dead bone fragments [3]. FRI, which occurs up to 30% of cases after complex open fractures, is the one of the most significant complication after fracture fixation and is associated with a significant socio-economic impact [4,5]. Therefore, one of the main objectives in the management of open fractures is infection prevention [6]. Overall, current evidence on the local application of antibiotics in the prevention of FRI is limited. Moreover, comparative studies on local antibiotics and carriers are nonexistent.

With this in mind, a recent comprehensive literature search was performed in PubMed, Web-of-Science and Embase [7]. Cohort studies investigating the effect of additional local antibiotic prophylaxis compared to systemic prophylaxis alone in the management of open fractures were included and the data were pooled in a meta-analysis. Following screening and confirmation of eligibility, 18 articles were available for analysis. Further review of these studies revealed the absence of a control group in 10 case-series. Finally, eight studies [8–15] with a total of 2,738 patients were eligible for quantitative synthesis. The effect of antibiotic loaded polymethyl methacrylate (PMMA) beads was investigated by six [8–13] of these studies and two [14,15] studies evaluated the effect of local antibiotics applied without a carrier. Meta-analysis showed a significantly lower infection rate when local antibiotics were applied than in the control group receiving standard systemic antibiotic prophylaxis alone. This effect was present in all three main Gustilo-Anderson types. However, when evaluated by the 'Grading of Recommendations Assessment Development and Evaluation (GRADE)' approach, it appeared that these results should be interpreted with caution due to the low rating of the recommendation.

This low rating implies the uncertain impact of heterogeneity and bias on the pooled data results [16]. Most studies used PMMA as a carrier for application of local antibiotics. The studies by Henry et al. [8] and Ostermann et al. [9,10] found a beneficial effect of locally applied tobramycin PMMA beads. This finding was supported by Keating et al. who reported a trend towards reduced risk of FRI with the addition of local tobramycin-loaded PMMA beads [11]. Ziran et al. also investigated the effect of tobramycin-loaded PMMA beads and reported a two-fold risk reduction in infection rate (31.3% vs. 16.7%) [12]. However, due to the small sample size, the study is associated with a considerable risk of bias and its results should be interpreted with caution. Conversely, the only randomized control trial (RCT) in this meta-analysis did not find any beneficial effect in preventing FRI with the use of tobramycin-loaded PMMA beads and even reported an increased risk of FRI (8.3% vs. 5.3%). However, this study, conducted by Moehring et al., is associated with a considerable risk of bias due to patient prognostic factors not being reported, inadequate case matching with regards to Gustilo-Anderson type and the absence of a clearly defined primary outcome [13].

Two studies investigated the effect of local antibiotics without a carrier [14,15]. In open articular tibial fractures, Singh et al. found no beneficial effect of topical vancomycin, although this study is associated with a considerable risk of bias due to a small sample size, inadequate reporting of soft tissue involvement and length of follow-up [14]. The advantages of topical vancomycin include widespread availability, low costs, efficacy against most common pathogens and limited concerns regarding inhibition of bone healing or osteogenic cytotoxicity [17]. However, there are concerns that in the age of widespread antimicrobial resistance, the use of vancomycin should be reserved for therapeutic, rather than prophylactic, purposes [15].

Lawing et al. investigated the effect of locally injected aqueous aminoglycosides in open fractures in a methodologically well-designed observational trial. They found a significantly reduced infection rate (9.5%) compared to the control group (19.7%). There was no obvious evidence that local aminoglycosides were inhibiting bone healing since they were not associated with a higher non-union rate [15]. O'Toole et al. recognized the missing evidence of topical vancomycin in extremity fractures as well and recently published a study outline of a planned multicenter RCT investigating its effect on FRI [17]. A qualitative analysis was performed on the ten studies [18–27] that were excluded from the meta-analysis for a lack of control group. Five of these studies investigated the effect of PMMA containing tobramycin [19,20,27] or the combination of tobramycin and vancomycin [21,23] and reported an infection rate from 0% to 20.0%. Chaudhary et al. assessed the efficacy of gentamicin impregnated collagen fleece in the treatment of open fractures in a case-series of 31 patients and reported an infection rate of 16.1% [25]. Cai et al. observed no infection in 26 open long-bone fractures treated with local vancomycin loaded calcium-sulfate pellets [24]. Three series reported no deep infection after treating in total 22 open tibia fractures with a poly (D,L-Lactide) (PDLLA)/gentamicin coated tibial nail [18,22,26].

Overall, we can state that most evidence regarding local antibiotic carriers is limited to studies using local PMMA beads. Indeed, antibiotic impregnated PMMA beads should not be neglected in the acute management of open fractures. PMMA is non-biodegradable and therefore requires surgical removal, which limits its application to cases that need a planned second-look operation. In addition, following the initial high antibiotic level release from PMMA, there is a prolonged low-level antibiotic release that may be below minimum inhibitory concentration (MIC) for potential pathogenic

organisms. This might initiate a selection pressure that favors the emergence of resistant strains, as well as a foreign body reaction [28]. As mentioned earlier there were also studies included in this review that administered antibiotics without a carrier. The main disadvantage of locally administered antibiotics without a carrier is that there is no controlled delivery of antibiotics directly into target tissues and no sustained release over a sufficient time interval [28]. Biodegradable carriers overcome this issue and do not have the limitations of PMMA. New absorbable biocomposites, such as gentamicin-loaded calcium-sulfate/hydroxyapatite, have shown to be highly effective in treatment of chronic osteomyelitis [29]. Malizos et al. demonstrated in a recently-published multicenter RCT that a fast-resorbable antibiotic loaded hydrogel significantly reduced infection rates after internal osteosynthesis of closed fractures [30]. However, evidence in clinical literature on the effectiveness of degradable carriers in open fractures is limited. Our literature search identified only five case-series analyzing the effect of biodegradable antibiotic carriers in open fractures. Even though these studies are associated with a considerable risk of bias, the overall results are promising: no infections were reported in 26 open fractures treated with vancomycin loaded calcium-sulfate pellets [24] and in 22 open tibia fractures stabilized with a gentamicin coated tibial nail [18,22,26]. The study by Chaudhary et al. did report some infections with the use of antibiotic impregnated collagen fleece [25].

In conclusion, this systematic review is providing an overview of most recent literature on local antibiotic prophylaxis in open long-bone fractures, including various new absorbable carriers [28,30,31]. The beneficial effect of local antibiotics in open limb fractures was proven by pooling data exclusively from cohort studies that compared the effect of additional local antibiotics to standard systemic antibiotic prophylaxis. With respect to the type of carrier that should be used, most available evidence exists on antibiotic-loaded PMMA beads. As PMMA has potential downsides, multiple biodegradable carriers have been recently developed and some of the new carriers seem promising (e.g., poly [D,L-Lactide] [PDLLA]/gentamicin coating, fast-resorbable antibiotic loaded hydrogel). The main limitation of this review and meta-analysis is the low quality of evidence available in the literature. RCTs of sufficient statistical power and bias limiting methodologies are required to corroborate the findings of this meta-analysis. Of critical importance is the reporting of trials in accordance to agreed minimum datasets and, in particular, the use of a standardized definition for FRI [32].

QUESTION 4: Is there a role for a combination of local and systemic antibiotic delivery systems to treat open fractures with overlying contaminated wounds?

RECOMMENDATION: The administration of systemic antibiotic and a local antibiotic delivery device (system) is an effective treatment strategy for open bone fractures with contaminated wounds.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 87%, Disagree: 4%, Abstain: 9% (Super Majority, Strong Consensus)

RATIONALE

The use of local antiseptic or antibiotic in the treatment of open bone fractures for infection prevention has a history of over 100 years, and this treatment approach continues today [1,2]. The use of systemic antibiotics for the treatment of open bone fractures is supported by landmark clinical studies by Patzakis, Harvey and Ivler, as well as Gustilo and Anderson [3,4]. Their early studies indicated that systemic antibiotic treatment was therapeutic and prophylactic in preventing wound infections in open bone fractures.

With the development of the addition of antibiotics, first in bone cement and later in other biomaterials, local antibiotic delivery for the treatment of open bone fractures became a therapeutic option for infection prevention [1,4–8]. While several recent reviews by Isaac et al., Warrender et al. and Gosselin et al. support the role of systemic antibiotic delivery in the treatment of open bone fractures [9–11], the 2014 systematic review by Craig et al. directly addresses the role of systemic and local antibiotic delivery in open tibia bone fractures [12]. Their study conclusion was,*"The findings support consideration of augmenting the antibiotic prophylaxis regimen to include locally delivered antibiotics. Patients with severe fractures will obtain greatest benefit from infections avoided"* [12]. Another key comment in the Craig et al. study conclusions is, *"No trial directly compared the two treatments for open tibia fractures, limiting the ability to attribute the differences in observed infection rates directly to the treatments themselves.* ***A large comparative study to improve the evidence on relative effect size is merited****"* [12]. A more recent meta-analysis by Morgenstern et al. concluded that there is a risk reduction with respect to infection of 11.9% if additional local antibiotics are given prophylactically for open limb fractures. Although the authors stated that due to limited quality, heterogeneity and considerable risk of bias, the pooling of data from primary studies has to be interpreted with caution [13].

Despite the lack of the mentioned direct comparison study and many other technical questions that range from antibiotic therapy duration to antibiotic selection, several retrospective studies do support the combination of systemic and local antibiotic delivery for infection prevention during the treatment of open bone fractures.

QUESTION 5: What is the most optimal antibiotic treatment for chronic osteomyelitis?

RECOMMENDATION: Antiobiotic selection should be culture-specific, if possible. No clear evidence exists to suggest that longer duration of therapy (12 to 16 weeks) is superior to shorter duration (4 to 6 weeks). In addition, there is no evidence to support the proposition that intravenous (IV) antibiotic treatment is superior to oral treatment.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 96%, Disagree: 4%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Chronic osteomyelitis remains a challenging problem in 2018. Recurrence of infection is common with a reported incidence of 20 to 30% [1,2]. The disease includes a vast spectrum of clinical scenarios that range from mandibular osteomyelitis arising as a result of dental complications, chronic vertebral osteomyelitis, post-surgical and post traumatic long bone osteomyelitis, pressure related chronic osteomyelitis of the pelvis, calcaneus and other sites as well as diabetic foot infections. Other disease processes also could be included in this group. Complicating the picture is the fact that these infections are caused by a multitude of pathogens and may be polymicrobial. Management of chronic osteomyelitis usually requires surgical debridement plus antibiotic therapy [3]. Because of variations in surgical approaches and the recent use of local antibiotic delivery devices, recent literature contains multiple variables that are difficult, if not impossible to control for, to determine what influence the systemic antibiotic played in the patient's outcome.

Antibiotic Choice

Older literature that includes randomized control trials (RCTs) often used an oral quinolone with a comparator parenteral agen [4–7]. Gentry and Rodriguez prospectively compared ciprofloxacin with cephalosporin or nafcillin plus aminoglycoside in 31 patients with biopsy proven osteomyelitis. These two populations had similar success rates of 77% and 79% respectively [4]. Mader et al. evaluated 26 patients with chronic osteomyelitis with oral ciprofloxacin vs. "standard parenteral therapy" consisting of nafcillin, clindamycin and gentamicin singularly or in combination. Both groups had similar success rates when evaluated two to three years after treatment [7]. Gentry and Rodriguez compared 19 patients with oral ofloxacin for 8 weeks with 14 patients with parenteral antibiotics for 4 weeks and found 74% and 86% success rates, respectively [5]. Gomis et al. evaluated 32 patients who had susceptible chronic osteomyelitis with oral oflaxacin versus imipenem-cilastin and found cure rates of 69% and 50%, respectively which were not statically significantly different [6]. Euba et al. compared 50 patients with Staphylococcal osteomyelitis comparing rifampin and clotrimoxazole combined versus IV cloxacillin for 6 weeks with oral cloxacillin for 2 weeks. Treatment outcomes in these two groups were similar and not statistically significantly different [8]. Norden et al. compared 19 patients with chronic post-traumatic chronic osteomyelitis using IV Nafcillin or cephalothin with IV nafcillin plus rifampin and found that cure rates were higher in the IV nafcillin plus rifampin group but this was not statistically different [9]. In the final RCT, Sheftel et al. studied ceftazidime vs. ticarcillin plus tobramycin for chronic gram-negative osteomyelitis in 18 patients and found cure rates of 67% and 89%, respectively [10].

Finally, Spellberg and Lipsky published a review of systemic antibiotic therapy for chronic osteomyelitis in Clinical Infectious Disease in 2012 [11]. Included in that summary were 49 non-RCTs that included 9 to 115 patients in each study with most studies having 20 to 40 patients each. The study populations were diverse and included patients with and without infected prostheses [11]. Surgical intervention was not universal in the studies and follow up was variable. Despite these limitations, some lessons can be learned. In the nonrandomized studies that included four to six weeks of a parenteral ß-lactam, the cure rates were 60-90% [1]. Cure rates were lower in patients that had chronic osteomyelitis with Pseudomonas [11]. Cure rates were also lower in studies where vancomycin was compared with ß-lactam agents for osteomyelitis caused by *S. aureus* [11]. Fluoroquinolones were the best studied antibiotic group for chronic osteomyelitis. Most studies reported cure rates of 60-80% [11]. Rifampin also improved outcomes in several studies when combined with fluoroquinolones and other active agents for chronic *S. aureus* osteomyelitis [11]. However, because of the numerous drug interactions with rifampin, there are times when it is not advisable to use rifampin. In addition, rifampin should never be used without another known active agent due to the rapid development of rifampin resistance that often occurs within just a few days. Regardless, the authors of this review were unable to recommend the best agent for treatment [11].

Duration of Administration

Traditionally, six weeks of parenteral antibiotic therapy was prescribed for chronic osteomyelitis combined with surgical debridement [12,13]. Yet there is no clear advantage in the literature that longer durations result in better treatment success than shorter durations. In a recent systematic review, most of the included antibiotic therapy that was given was high-dose and administered for 12 to 16 weeks [11]. However, the available data in these studies is inconclusive to know if the higher doses or prolonged therapy improved outcomes [11]. At this time, the literature does not offer adequate evidence to determine the optimal duration of antibiotic therapy for chronic osteomyelitis [2,11,14,15].

Route of Administration

Recent evidence has shown that oral antibiotic therapy may be equally as effective as parenteral antibiotic therapy [2,11,15]. Conterno et al. conducted a Cochrane systematic review on antibiotics for treatment of chronic osteomyelitis in adults [2]. This review included RCT or quasi-RCTs regarding antibiotic treatment used after surgical debridement of chronic osteomyelitis in adults. They found no difference between oral and parenteral antibiotic therapy. This review was an update of a prior 2009 Cochrane review [16]. They concluded that the quality of evidence available was limited to make a definitive conclusion regarding antibiotic treatment of osteo-

myelitis [2]. In the aforementioned review, Spellberg and Lipsky suggested that chronic osteomyelitis can be effectively treated based on the antibiotic susceptibility of the pathogen(s) and pharmacokinetics with oral antibiotics as well as parenteral therapy. They concluded that oral antibiotic therapy with the proper agent was an effective alternative to parenteral antibiotics [11].

Conclusion

While the studies to date do not provide a clear optimal antibiotic choice, duration or route of administration for the treatment of chronic osteomyelitis, some observations are consistent from the data available. First, knowing the pathogen, pathogen sensitivities, antibiotic bone penetration and antibiotic toxicities do help the treating physician make the best choice for a specific patient and clinical scenario. It is important, whenever possible, to establish a microbiological diagnosis (or at least to obtain adequate bone tissue for culture in the lab) prior to initiating antibiotics. As the current recommendation for duration of therapy is typically 4-12 weeks, antibiotic exposure and toxicity can be significant. Second, in certain situations, oral therapy is just as effective as parenteral therapy and there are more studies supporting oral therapy than parenteral therapy. There is sufficient data to support the use of an active oral fluoroquinolone for osteomyelitis caused by gram-negative organisms, the use of an active fluoroquinolone with rifampin for *S. aureus* osteomyelitis, and the consideration of using trimethoprim-sulfa with rifampin for *S. aureus* osteomyelitis if both agents are active. Using an active fluoroquinolone alone for *S. aureus* osteomyelitis should be avoided due to the development of resistance while on monotherapy and the higher rate of relapse after therapy is completed. Third, adding rifampin to a variety of antibiotics seems to improve cure rates when coupled with another known active agent when treating *S. aureus* osteomyelitis. Fourth, surgical debridement and removal of infected hardware, when possible, generally improves treatment outcomes. Fifth, oral clindamycin which is routinely used for the treatment of acute *S. aureus* osteomyelitis in children [17–20], has not been well studied for the treatment of chronic osteomyelitis in adults. Finally, it is also important to keep in mind that antibiotics are only effective when they reach the site of infection. Adequate vascularized soft tissue coverage of infected bone, debridement of any significant necrotic tissue and sequestrum, and adequacy of blood flow to the affected site are likely critical factors in improving outcomes.

Clearly, additional RCTs are needed to answer the question regarding the optimal agent, route and duration of therapy for treating chronic osteomyelitis in adults.

QUESTION 6: What is the recommended suppressive antibiotic therapy for the treatment of chronic osteomyelitis after fracture fixation when the implant cannot be removed?

RECOMMENDATION: Suppressive therapy with culture-specific antibiotics is aimed at allowing fracture healing prior to implant removal and definitive infection management.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Infection after surgical treatment of fractures is a complication with significant morbidity, and in rare cases even mortality. Infections have often been classified according to the time interval between surgery and occurrence, although the distinction between acute and chronic infections has recently been challenged. Early infections are mainly caused by virulent microorganisms, such as *Staphylococcus aureus*, and diagnosed within the first three weeks of surgery. Delayed infections are typically due to less virulent bacteria, such as coagulase-negative Staphylococci, and develop between 3 and 10 weeks. Finally, late infections, occur after 10 weeks and are either caused by haematogenous seeding or by recurrence of inadequately-treated early infection [1]. Infections that occur following open reduction internal fixation (ORIF) are typically caused by biofilm-forming bacteria, which adhere to the implants [2]. In approximately one week, a mature biofilm already forming, which makes it less likely to for antibiotics alone to eradicate bacteria [3].

Common treatment for implant-related infection obeys to three established principles: surgical debridement, antibiotic therapy and eventual implant removal or staged exchange. However, in ORIF and with fracture-related infection (FRI), implant removal is unsuitable because of resulting fracture instability that often leads to prolonged infection [4,5]. This has consequences for the other aspects of treatment – if the implant is retained, the biofilm remains. Surgical debridement can remove the bulk of the bacterial load, but adjuvant antibiotic therapy must be directed towards the biofilm present. If the implants are retained, treatment consists of thorough surgical debridement, tissue cultures and long-term antibiotic suppressive therapy with rifampin-based combination antibiotic therapy. To date, only two classes of drugs have shown the properties that are needed for control of biofilm forming bacteria. Rifampin and other rifamycins act on biofilm active Staphylococci [6–11] and fluoroquinolones on gram-negative bacilli [12,13].

In the event of retained hardware after debridement of an acute infection following ORIF, the recommended antibiotic combination therapy should start immediately after the first surgical intervention and consists of 10 days of intravenous (IV) vancomycin and rifampin. Vancomycin was the agent of choice for empirical therapy because of its activity against a broad spectrum of microorganisms, the high incidence of gram-positive infections and the synergetic effect with rifampin [14–16]. Vancomycin therapy was started twice daily (1,000 mg IV), and was adjusted to maintain serum levels between 15 and 20 mcg/ml. Rifampin was given twice daily (450 mg IV). After tissue cultures identify the responsible bacterial pathogens and susceptibility data becomes available, vancomycin therapy can be switched to another, narrow spectrum antibiotic as indicated. Rifampin is continued unless rifampin-resistant bacteria are found.

Zimmerli et al. [2,6] assessed the effectiveness of this protocol in a randomized controlled trial, and after the IV administration period, oral combination antibiotic therapy with rifampin was continued for ten additional weeks. They reported 100% success in cases where both antibiotics were administered compared to 58% success when only ciprofloxacin was received. Barberan et al. [17] and Drancourt et al. [18] also studied infection following ORIF and evaluatied the effect of antibiotic combination therapy with rifampin reporting good results. Drancourt et al. [18] analyzed both periprosthetic joint infection (PJI) and FRI treated with initial retention and combination antibiotic therapy, and reported a success rate of 48% after an average follow-up of 23.5 months. The study of Barberan et al. [17] only included patients with infections following ORIF and demonstrated a success rate of 72%. In a prospective observational cohort study, Tschudin-Sutter et al. [19] analyzed 233 patients with orthopaedic implant-related infections of which 52.4% (122/233) were infections related to ORIF, for which the success rate was 90.2% (110/122) with the use of rifampin-combination regimen as suppressive therapy. This was seen on patients with implant retention after two years of followup. Patients were identified for inclusion using strict selection criteria (the duration of clinical symptoms was no longer than three weeks): stable implant, intact soft tissues, no abscess or sinus tract and the causative pathogen was susceptible to antibiotics with activity against surface-adhering microorganisms (i.e., rifampin for *S. aureus* or coagulase-negative Staphylococci and ciprofloxacin for gram-negative pathogens) [19]. This is so far the largest study evaluating patients with implant-associated infection managed with retention and long-term suppressive antibiotic therapy.

It is important to highlight the critical aspect of implant stability, as loose implants cannot be retained even if infection becomes evident at very early stages. Worlock et al. [4] demonstrated in a rabbit model that unstable tibial fractures were associated with significantly higher rates of osteomyelitis than those which were stable. These implants can often be retained when an acute infection develops after fracture fixation. Implant removal is generally undesirable in cases of acute infection as ORIF serves two different goals. First, the stability achieved by fixation is critical for fracture healing. When conditions are created in which micromotion between bone fragments is possible, resorption and necrosis of the affected bone will occur [5]. Second, the aim of operative fracture management and early mobilization is to prevent loss of function due to scarring of the surrounding soft tissue or joint stiffness. Special consideration should be given to infections after intramedullary fixation, with the popular belief that eradication of the infection is not feasible without implant exchange [20]. Chen et al. [21] reported on 23 infections following intramedullary (IM) nailing of the femur for fractures. The patients were divided into two groups where one group with IM nails had their nails removed and an external fixator was placed. All femur fractures with retained IM nails healed (12/12) and were infection free at followup of average 25 months. Only 7 of 11 patients (64%) in the external fixator group healed. Whereas removal or exchange of the implant provides the opportunity to remove the biofilm and thus reduce the bacterial load, in cases of implant retention the surgical debridement and adjuvant antibiotic therapy play a more important role.

In conclusion, in the situation of FRI where debridement and implant retention is chosen as the treatment strategy, rifampin (rifamycins) can be an effective adjuvant agent in suppressing gram-positive organisms while ciprofloxacin (fluoroquinolones) can be effective in suppressing gram-negative organisms.

Author: Leonard Marais

QUESTION 7: Is there a role for hyperbaric oxygen therapy (HBOT) and other non-antibiotic methods for the treatment of chronic osteomyelitis/implant infections?

RECOMMENDATION: There is limited evidence for the efficacy of hyperbaric oxygen (HBO) in the treatment of post-traumatic bone infections.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 86%, Disagree: 5%, Abstain: 9% (Super Majority, Strong Consensus)

RATIONALE

HBOT has been proposed as an adjunctive therapy in the management of refractory osteomyelitis, which was defined as chronic osteomyelitis that persists or recurs after appropriate interventions have been performed or where acute osteomyelitis has not responded to accepted management techniques [1]. The procedure involves the intermittent inhalation of 100% oxygen in chambers pressurized above one atmosphere absolute (typically to about 2 to 2.5 atmosphere absolute (ATA)). It is based on the premise that increased tissue oxygen levels will enhance healing. Although adverse events are typically self-limiting, more serious potential complications include baro-traumatic otitis, pneumothorax, myopia and seizures [2].

While initially there was some enthusiasm about the use of HBOT in refractory osteomyelitis, this appears to have waned with only one case series published since 2004 [3]. Prior to this, a small number of descriptive studies were published that reported encouraging results [4,5]. A systematic review by Goldman in 2009 examined the evidence for HBOT in wound healing and limb salvage. Five studies were classified as "moderate" strength evidence (the remaining 10 being either "low" or "very low") [6]. In the first of these Morrey et al., reported on the outcomes of HBOT in 40 patients who had recurrent infection for more than 6 months after at least 1 surgical procedure [7]. Following surgery, antibiotics and HBOT, 85% of patients were reported to be disease-free at one year.

Davis et al. performed a retrospective study on 38 patients with actively draining wounds and at least 1 failed previous surgical procedure [8]. Complete healing was achieved, again in combination with surgery and antibiotics, in 89% of cases. From 1998 to 2004 Chen et al., published three overlapping case series involving patients who presented with recurrence of infection following prior surgical treatment [9–11]. The success rate of standard treatment, involving aggressive debridement, antibiotics and HBOT, was reported as 79% to 92% (note that the 2003 study was not included in the Goldstein systematic review). The findings from all of these non-comparative studies are however difficult to interpret and confounded by the fact that HBO was used as part of a multi-modal treatment strategy. Furthermore, it is not clear if the initial failed surgical procedures were performed by experienced musculoskeletal infection surgeons. There was only one comparative study included in the Goldman systematic review. Esterhai et al. performed a prospective non-randomized controlled trial and found that HBOT had no effect on length of hospitalization, initial clinical outcome or the late recurrence of infection [12]. The only clinical study published since the systematic review in 2009, described the experience of a single center with HBOT in general and did not provide a detailed description specific to the chronic refractory osteomyelitis patients [3].

Recently, the effect of HBOT on implant-associated infection was further drawn into question. Büren et al. illustrated in a standardized murine model that HBOT did not have a beneficial effect on the local infection or the immune response to the infection compared to standard therapy alone [13]. Interestingly, they also noted delayed bone healing and a higher rate of non-unions at 28 days in the HBOT group. Ultimately, there is currently only limited evidence

supporting the use of HBOT in post-traumatic infections and the single study with a control arm reported no benefit.

3.2. TREATMENT: SURGEON AND CARE TEAM

Authors: Konstantinos Malizos, Georgios Komnos

QUESTION 1: Should all infected non-unions be treated in specialized septic centers?

RECOMMENDATION: The current literature, although rich in case series and observational studies, does not lend support to the recommendation that "specialized septic surgery centers" should care for infected non-unions. However, because of the complexities of infected non-unions, care in specialized centers may yield the best possible outcome.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 70%, Disagree: 21%, Abstain: 9% (Super Majority, Weak Consensus)

RATIONALE

Infected nonunion is the persistence of an infection at the fracture site and the surrounding tissue and failure of bone healing for eight months, (U.S. Food and Drug Administration). It could be considered as an osteomyelitis at an unstable fracture before the debridement and which remains unstable thereafter. It is commonly accompanied by soft tissue problems, adjacent joint stiffness, motor and sensory dysfunction of the limb, chronic pain, depression and unrelated medical problems leading to considerable physical, social, financial and mental impact on the life of the patient and the healthcare systems and may even become a limb-threatening complication.

Bone healing and eradication of the infection is the main but not the only objective because a non-functional and deformed limb with pain and stiffness of the adjacent joints will be an unsatisfactory outcome even if at some point the bone heals sufficiently. Treatment is aimed at returning the extremity and the patient to the fullest function possible during and after the treatment process. This process is usually long-lasting and must be planned accordingly so that in case of failure, further treatment alternatives remain available. Because of the various nonunion types and the multitude of possible problems related to the patient's health and comorbidity, such as prior treatments and the bone and soft tissue defects, no simple treatment algorithms are possible. The recommended strategy, with an array of management alternatives, is: (a) the "infection-elimination first" by local radical debridement of all pathological tissue, followed by (b) tissue and bone reconstruction and (c) targeted chemotherapy with local and systemic antibiotics.

A specialized team of orthopaedic surgeons with expertise in a broad spectrum of techniques must thoroughly evaluate the patient and carefully consider all available information about the general health status and the local tissue conditions. The prior failed treatments must be taken into account, as well as the optimization of all treatment modifiers. Where extensive surgical exposures have failed consideration is given to less invasive techniques that respect the surrounding soft tissues. Stable fixation, adequate vascularity, bone-to-bone contact, and bone grafting or strong bone regenerate are crucial factors for success. The potential need for future treatment should be considered when pursuing any particular intervention.

The care of the patients with infected nonunions may be best performed at specialized septic surgery centers with an expert team approach to achieve the ultimate goals of bony union and restoration of alignment and function, while limiting the extent of residual disability. A medical center that treats infected nonunions should provide all of the appropriate resources and a supportive team of consulting specialists to contribute to all aspects of care, both at the initial evaluation and throughout the course of treatment. The role of anesthesiologists is obvious as well as of the internists for patients with serious medical conditions. Plastic surgeons are often necessary to reconstruct the soft tissues

after serial debridement and vascular surgeons may be required if the vascularity of the limb is in question. A multidisciplinary treatment team should be utilized in providing comprehensive care, including a pain management specialist, a psychiatrist to support patients with clinical depression, a neurologist to evaluate motor or sensory loss, a dietician to optimize the nutritional status, and physical and occupational therapists to facilitate rehabilitation. Microbiology and histopathology labs with the availability of modern diagnostic facilities, an experienced clinical pharmacologist and an infectious disease specialist are all integral parts of the multidisciplinary unit as well.

APPENDIX - SEARCH STRATEGY

There is no study in the literature that has evaluated this particular issue. We have conducted a broad literature search trying to identify articles or parameters that could lead us to musculoskeletal infection specialist centers, although the number of true, dedicated centers with multi-disciplinary units at this time remains very low. Medline, Cochrane, and Embase databases were searched, employing the terms: "infected nonunions," "septic nonunions," "specialist's septic centers," "infected nonunion AND hospital" and "infected nonunion AND septic center." After removing papers that did not match our criteria we ended up with 69 articles, which were all observational case series for infected nonunions. Out of those we identified 28 articles (all level IV) that could be used for our analysis. Hospitals with level I trauma centers that had a minimum of two publications about infected nonunions were classified as "specialist centers" (group A) [1–15]. Orthopaedic departments with only one publication were categorized as "non specialized septic centers" (group B) [16–28].

In total, there were 15 publications from 10 centers in group A, and 13 publications from an equal number of centers in group B. Regarding the different treatment methods, in group A, 60% reported using external fixator to stabilize the nonunion, 20% used open reduction and internal fixation (ORIF), 6% intramedullary (IM) nailing and the remaining used more than one technique. In 67% of the patients in group A a bone graft was used, whereas in group B only 38% mention using bone grafting. For the fixation of the bone in group B, in 54% external fixation were applied, 15% used IM nails, 7.7% ORIF, while the rest report the use of more than one technique (external fixators and plates). Most studies do not report the length of hospital stay and time for return to work. In addition, not all of them give data about limb shortening and alignment. The average number of patients in the studies was relatively small. Given also the heterogeneity of anatomical locations of the nonunions among the different studies, valid comparisons are not possible. The number of previous operations was comparable: 2.9 in group A, and 3.1 in group B.

In 54% of group A centers, the infected nonunions were treated in one stage and 46% in two stages. In group B, 73% of the patients were treated in one stage and 27% in two stages. Thirteen studies analyzed the outcomes of treatment with the Ilizarov method, nine studies analyzed the management with a single-stage or two-stage approach and use of cancellous bone grafting, three studies involved vascularized bone grafting, and one study involved a bulk allograft. Follow-up was higher in group A (46.4 months) compared to group B (37.3 months). Both groups demonstrated similar outcomes with respect to the elimination of infection. However, parameters such as length of hospital stay, time to bone healing, time until return to work, functional outcomes and patient reported outcome measures are not available, thus markedly limiting the strength of the recommendation.

QUESTION 2: Is there a minimum number of complex osteomyelitis procedures a surgeon should perform annually to ensure proper outcomes?

RECOMMENDATION: There is no literature supporting a minimum number of complex osteomyelitis procedures a surgeon should perform annually to ensure proper outcomes. Higher-volume referral centers, centers of excellence and multidisciplinary teams for the treatment of complex osteomyelitis may result in improved outcomes.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 76%, Disagree: 14%, Abstain: 10% (Super Majority, Strong Consensus)

RATIONALE

In the literature reviewed, there is no evidence to answer the question. Osteomyelitis is a complex pathology, which needs years of follow-up to be able to demonstrate the sustained remission of the disease. Osteomyelitis has multiple etiologies: 19% hematogenous, 47% secondary to a contiguous focus and 34 % due to vascular insufficiency [1]. There is no evidence to establish the optimal duration of treatment and many studies do not present good-quality data and include a small number of patients [1,2]. Therefore, most of the recommendations for the treatment of osteomyelitis is based on expert opinions.

In joint arthroplasty, high-volume centers, multidisciplinary teams and centers of excellence have been shown to improve patient outcomes with respect to the treatment of prosthetic joint infections [3]. In trauma, there have been few studies looking at the benefit of high-volume centers for the treatment of complex osteomyelitis and septic nonunions. Bauer et al. retrospectively evaluated the results of a French referral center for complex bone infections. They had 55 patients over the course of 10 years who were treated for infected non-unions of the tibia or femur. They showed that 89% of patients with an infected tibial or femoral non-union treated by a team specialized in complex bone and joint infections using a standardized surgical protocol had bone union and healing of the infection in an average of nine months [4]. In a similar study, Bose et al. reported on 67 long bone infected non-unions over 6 years treated by a multidisciplinary team. They found that 59/67 (88%) went on to fracture union and eradication of their infection [5]. Lastly, Salvana et al. treated 82 patients over 7 years with chronic osteomyelitis with an integrated team approach and found successful union and limb salvage in 77 (94%) cases [6]. In these three studies, the centers treated on average 6-12 cases of complex osteomyelitis per year. At this time there is no data supporting a minimum number of cases of complex osteomyelitis a surgeon should perform annually to ensure good results, but having greater experience collectively at an institution or within a dedicated unit would presumably results in the greatest likelihood of a successful outcome in this difficult cohort of patients.

QUESTION 3: Who are the essential members of the multidisciplinary team required to manage infected fractures and non-unions?

RECOMMENDATION: The essential members of the multidisciplinary team managing infected fractures and non-unions require expertise in bone reconstruction, soft tissue reconstruction, microbiology, antibiotic treatment and advanced imaging. It is important to note that the exact members of the group and other specialists required will eventually depend on patient needs and local preferences.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

There is increasing evidence that teamwork and collaboration among healthcare workers are essential to improving patient outcomes [1,2]. Therefore, it is important to implement a multidisciplinary approach in treatment algorithms of fracture-related infec-

tions (FRI). The use of an antibiotic stewardship program is already a well-known concept for the management of different infection-related entities. These are defined as coordinated interventions designed to improve and measure the appropriate use of antibiotic agents by promoting selection of the optimal regimen, including dosing, duration of therapy and route of administration [3]. With its multidisciplinary approach, an antibiotic stewardship program improves patient safety and outcomes, and when combined with reduced readmission rates, reduces healthcare costs without compromising the quality of care [4–6]. Rodriguez et al. evaluated an evidence-based protocol for antibiotic prophylaxis in open fractures [7]. They demonstrated a short course of narrow-spectrum antibiotics (avoiding the use of broad-spectrum aminoglycosides and glycopeptides) does not increase the risk of soft tissue and skin infections after an open fracture.

Following the Infectious Diseases Society of America guidelines, infectious disease (ID) physicians and clinical pharmacists are the core members of antibiotic stewardship programs, but microbiologists and the implementation of administrative and information technology can also be of great importance [8]. However, as recently stated by Pulcini et al. [9], the composition of these teams is flexible and should be based on existing international recommendations and adapted to the local context based on resources available. Regarding the multidisciplinary approach to FRI, the treatment is based on two pillars: surgical management and clinical management.

Where the surgical management plays an important role, it seems imperative that surgeons (including musculoskeletal trauma surgeons and plastic surgeons) act as central members. Nevertheless, studies within this field are scarce. A multidisciplinary approach, which is constituted of collaboration between musculoskeletal trauma surgeons, the hospital's infection control department, nurses and anesthesiologists as primary team members, has been described to guide FRI prevention strategies [8].

With respect to treatment of FRI, a recent systematic review by Bezstarosti et al. (unpublished data) showed that out of the 93 included studies conducted between 1990 and 2017, only 12 studies (13%) discussed the members that were involved in their multidisciplinary team, with a wide variety of team members available: musculoskeletal trauma surgeons (10 studies), plastic surgeons (5 studies), ID physicians (5 studies), pharmacists (1 study), radiologists (1 study) and not further specified members (3 studies) [10–21]. A study by Bose et al. [12] obtained good results with a multidisciplinary team comprised of orthopaedic surgeons, plastic surgeons, radiologists and ID physicians for treating patients with infected nonunions of long bones [12]. It is important to note that most of the above-mentioned treatment studies focused on chronic/late FRI patients. A study by Dudareva et al. [22] reported a multidisciplinary approach allowed for successful treatment in the majority of cases with osteomyelitis of pelvic bones. The team members in this study were comprised of orthopaedic surgeons, plastic surgeons, and ID physicians. The team was completed by the contribution of specialized nurses, physiotherapists, occupational therapists and musculoskeletal radiologists.

In conclusion, although data specifically focusing on FRI is scarce, a collaboration of different specialties most likely would improve the outcomes in this difficult patient population. No study has evaluated the specific essential participants, but do mention the results with involved members. Antibiotic stewardship programs have already proven their use by means of a multidisciplinary collaboration between ID specialists, clinical pharmacists and microbiologists. The same approach should be applied to set up a main treatment plan for the FRI patient, including surgical, antibiotic and clinical aspects.

3.3. TREATMENT: RISK FACTORS

Authors: Paddy Kenny, Giedrius Kvederas, John Gibbons

QUESTION 1: What are predictors of the need for allogeneic blood transfusion (ABT) in periprosthetic fractures?

RECOMMENDATION: Predicting factors for allogeneic blood transfusion are: revision arthroplasty, preoperative anemia, increasing age, higher comorbidity index, lower Body Mass Index (BMI), female gender, longer surgical time and hip surgery.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 95%, Disagree: 5%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

There is little data regarding predictors of the need for ABT in periprosthetic fractures. Periprosthetic fracture studies typically include a low number of patients, and conclusions about covariates are often not available. These fractures may be treated by either revision surgery or open reduction and internal fixation (ORIF). General indications for ABT in total joint arthroplasty (TJA) can be identical in the first group.

Slover et al. demonstrated that hip arthroplasty had a significantly higher likelihood of blood transfusion (odds ratio (OR) 1.76, 95% confidence interval (CI), 1.68 to 1.83) than knee arthroplasty. Increasing age (age ≥ 80 years; OR, 2.99, 95% CI, 2.82 to 3.17), Medicaid insurance (OR, 1.36, 95% CI, 1.27 to 1.45), higher comorbidity index (score of ≥ 3, OR, 2.33, 95% CI, 2.22 to 2.45), and females (OR, 1.75, 95% CI, 1.70 to 1.80) all had significantly higher odds of blood transfusion after TJA [1].

Parvizi et al., reported that advanced age, low BMI, simultaneous bilateral arthroplasty and low preoperative hemoglobin were independently associated with increased rates of ABT [2].

In a study by Rasouli et al., one-stage bilateral TJA (OR, 3.30;, 95% CI, 3.24 to 3.37; $p < 0.001$), anemia due to chronic blood loss (OR, 2.69, 95% CI, 2.59 to 2.74, $p < 0.001$), deficiency anemia (OR, 2.59; 95% CI, 2.56-2.62; $p < 0.001$) and increased Charlson comorbidity index (OR, 1.24, 95% CI, 1.23 to 1.24; $p < 0.001$) were independent predictors of allogeneic blood transfusion [3].

In the study by Solon et al., 12 patients with Vancouver B2 periprosthetic fractures around cemented collarless polished tapered (CCPT) stems treated by ORIF alone (median follow-up 67 months) were compared with those of nine patients with a similar fracture treated by revision surgery. All 12 patients with Vancouver B2 femoral fractures around CCPT stems treated by ORIF alone healed and all stems restabilized and remained stable within their original cement mantle. These patients had significantly shorter surgical times ($p = 0.002$) and required fewer units of blood transfusion ($p = 0.008$) than patients in the revision cohort [4].

Saidi et al. evaluated 3 different surgical methods for treating comminuted distal femoral periprosthetic fractures in 23 patients over the age of 70 (average age 80, range 70-90). Reconstruction techniques included seven allograft prosthesis composites (APC), nine revision systems (RSA), and seven distal femur replacements (DFR). Operative time and blood loss were found to be significantly less in RSA and DFR patients compared to the APC patients [5], suggesting that more ABTs are required in complex revisions for periprosthetic fractures [5].

Min et al. retrospectively evaluated the clinical and radiographic outcomes of a series of 21 Vancouver type B1 periprosthetic femur fractures (PPF) treated with minimally invasive plate osteosynthesis (MIPO) and locking compression plate (LCP) between February 2011 and February 2017. The mean duration of follow-up was 33.8 months. They also compared outcomes of these patients to similar patients with 19 Vancouver type B1 fractures treated with ORIF between April 2006 and December 2011. The authors found that operative time was significantly shorter and intraoperative blood loss was significantly less in the MIPO group compared to the ORIF group [6].

Fulkerson et al., showed that percutaneous fixation of PPFs with the Less Invasive Skeletal Stabilization (LISS) plate is an effective although technically demanding method of treatment with minimal blood loss [7]. Thomas et al. also had similar results with the LISS plate [8].

Blood loss was minimal and only two of ten patients needed a blood transfusion with Vancouver type B1 fractures treated with percutaneous cerclage wiring for fracture reduction and maintenance of reduction with MIPO utilizing an LCP [9].

QUESTION 2: Is acute femoral neck fracture a risk factor for infection in patients undergoing hip arthroplasty?

RECOMMENDATION: There appears to be a higher incidence of infection in patients undergoing arthroplasty for acute femoral neck fracture compared to hip arthroplasty for primary osteoarthritis. The reported rate of infection has a wide range; prospective studies should be performed to determine the true rate of periprosthetic joint infection (PJI) in this subset of patients.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 96%, Disagree: 4%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

A study on 58,000 elective, primary total hip arthroplasties (THAs) demonstrated a deep surgical site infection (SSI) rate of 0.2% [1]. There are multiple studies reviewing the outcomes of treatment for femoral neck fractures. Most of the studies are retrospective reviews of small cohorts that are not sufficiently powered to study infection rates. Additionally, many of the studies merge primary hemi or total arthroplasty patients with patients who underwent open reduction and internal fixation, and then subsequently a secondary arthroplasty procedure. While most studies report infection rates, the primary endpoint tends to aim at a controversy in treating these fractures, such as cemented versus cementless, or performing hemiarthroplasty versus total arthroplasty. Infection rates vary from 1.2% to 4% [2–5]. A study on 90-day costs following hemiarthroplasty or THA for treatment of hip fractures demonstrated a 17.7% infection rate, but this was not limited to surgical site infections; urinary tract infections, pneumonias and other infections are included in this percentage [6]. A meta-analysis on outcomes of patients who sustained femoral neck fractures reported a 1.0% SSI rate in patients undergoing THA, 1.7% SSI rate in patients undergoing bipolar hemiarthroplasty and a 2.8% SSI rate in patients undergoing unipolar hemiarthroplasty [7].

A study from the Swedish Hip Arthroplasty compared 10,264 patients who underwent THA for treatment of a subcapital hip fracture with 76,520 patients who underwent THA for other reasons and they reported a 0.5% infection rate in the patients who were treated for fracture [8]. It appears that the rate of infection is higher in patients undergoing arthroplasty surgery for the treatment of acute femoral neck fractures.

3.4. TREATMENT: PROCEDURE-RELATED

Author: Pedro Caba

QUESTION 1: What is the optimal timing of surgical debridement in open fractures?

RECOMMENDATION: It is not possible to establish a clear cut-off for optimal timing of open fracture surgical debridement after injury. Administration of antibiotic prophylaxis and adequacy of debridement is more important than time to debridement. However, we recommend debridement as soon as the patient and operative conditions are optimal.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Debridement is only one of the main pillars of initial open fracture treatment. Antibiotic therapy and proper fixation are also important variables. It is difficult to separate the effects of the different treatments and actions on the onset of infection and other complications. Most clinical studies demonstrate small differences in the time to debridement between comparison groups, and time cut-offs are arbitrary based on historical papers. The implementation of early antibiotic treatment in open fracture treatment has changed the infection rate. Examining the relationship between timing of surgical debridement and infection risk is crucial in guiding clinical practice, as there is still significant variability among surgeons' preferences. Most of the orthopaedic doctrine in this issue is based on historical papers or retrospective studies.

The cut-off of six hours for initial surgical debridement is based on the 1898 Friedrich study which demonstrated in an animal model that wounds debrided within six hours had no infection. This finding became incorporated into orthopaedic doctrine as the "6-hour rule." Robson supported these findings with a clinical study in 1973. He described a golden hour or inflection point of 5.17 hours after injury, which is the time needed for bacteria to reach a critical level of contamination ($> 10^5$ bacteria per gram of tissue specimen).

The first systematic review examining the relationship between infection and time to debridement was published in 2012 [1]. This review included 3,539 patients from various studies. The analyzed data did not indicate an association between delayed debridement and higher infection rates. Studies published since 2012, including a metanalysis, indicate that the 6-hour rule is not supported by evidence. Prodromidis performed a metanalysis in 2016 on the specific topic of the 6-hour rule in open tibia fractures [2]. This paper examined seven articles (only two prospective) involving 610 patients. The statistical analysis did not find any differences in terms of deep infection or non-union regarding the time to debridement.

One major limitation in this literature is the arbitrary cut-off times in the different studies. In 2014, the results of a large prospective cohort multicentre study involving 797 fractures was published. This study did not demonstrate differences in the early (< 6h), intermediate (6-12h) and late (> 12h) groups. Median time to debridement was 9h 15 min, indicating that most patients were not treated early. Another prospective study published by Srour et al. reported similar results [3]. They studied a cohort of 351 consecutive patients treated in the same facility comparing three different cut-off times (< 6 h, 6-18h and 18-24 h). They concluded that the time to operating room did not affect the development of local infectious complications, provided that the operation was performed within the first 24 hours after arrival.

Recent papers have focused on the impact of delayed debridement on infection rates, with conflicting results. Kumar et al. performed a large retrospective study of 404 patients treated with contemporary treatment. They reported that the rate of infection in open lower extremity fractures increases when debridement is delayed beyond eight hours [7]. For upper extremity injuries, delayed debridement did not result in any increase in infections. Penn-Barwell, in an experimental study on rats [8], demonstrated the timing of antibiotics had a more significant effect than surgical debridement on the onset of acute infection, especially when initation of treatment is delayed beyond six hours. When antibiotics were started at two hours, a delay in surgical treatment from two to six hours significantly increased the risk of development of infection but delays beyond six hours did not result in any increase in infection indicating that very early debridement, within two hours of the injury, could have a positive effect. Hull et al., in a prospective series of 459 patients, studied the relationship between delayed debridement and deep infection [6]. They reported that there is a 3% increased risk of infection for every hour of delay. As baseline infection risk is higher for Type IIIB and IIIC open tibia fractures than for lower grade tibia fractures, the increased risk in this group of fractures is much higher when the debridement is delayed. According to this study, the predicted probability of infection in a high grade contaminated tibia fracture increases from 35% at four hours post-injury to 45%. They recommend urgent debridement at the first reasonable opportunity after injury.

In summary, urgent debridement is essential in the initial treatment of open fractures, but the cut-off time is not known. There is little current evidence supporting the 6-hour rule. There is moderate evidence supporting the proposition that delayed debridement beyond eight hours could have an impact on infectious complications, especially in high-grade open tibia fractures. There is only limited evidence supporting very early debridement (< 2hrs).

QUESTION 2: What is the recommended volume of irrigating fluid in the emergency department (ED) for open fractures?

RECOMMENDATION: In the ED setting, open fractures should be irrigated sufficiently to remove all visible contamination and debris prior to applying dressings.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 75%, Disagree: 15%, Abstain: 10% (Super Majority, Strong Consensus)

RATIONALE

Search Method: A comprehensive literature review was performed to identify all studies on the use of irrigation for the treatment of open fractures in the ED. We searched Ovid Medline, Scopus, and the Cochrane Central Register of Controlled Trials (CENTRAL) up to May 2018 for published studies. Search strategy, including keywords and MeSH headings, are provided in the Appendix. Eligible studies met the following criteria: (1) all patients included in the study had an open fracture, (2) infection was an outcome variable and (3) irrigation in the emergency setting was the intervention. Exclusion criteria were non-English language articles, nonhuman studies, retracted papers, case reports, review papers, studies without clinical follow-up/infection rates, and technique papers without patient data. Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) criteria were followed. The initial search resulted in six papers. After removal of duplicates and screening of titles and abstracts, one article was assessed and reviewed.

RATIONALE

Thorough irrigation is a cornerstone in the treatment of open fractures. It is an important step in decreasing bacterial load and removing foreign bodies. Despite extensive literature in the management of open fractures, there has been very little data on the role of wound irrigation in the ED prior to formal debridement in the operating room. Furthermore, the literature is lacking with regard to the optimal volume of irrigation during formal debridement in the operating room [1].

One study by Basat et al. looked retrospectively at clinical outcomes of patients with open fractures of the hand treated with antibiotics and irrigation in the ED alone without formal irrigation in the operating theater. Irrigation with sterile saline was performed by the orthopaedic surgery resident, until the wound was grossly clean. The volume of irrigation and degree of wound contamination were recorded. Of the 68 open fractures treated, 14.8% developed an infection. They found that volume of irrigation correlated with development of infection, with 70.5% of fractures requiring > 1,000 ml of irrigation. They concluded that in the ED, one should use as much fluid as needed to obtain a grossly clean wound. However, this study clearly has its limitations. The degree of contamination is a highly subjective and confounding variable in the association found between increased irrigation volume and increased infection rate. This study looked at open factures of the hand, which are different from those of the lower extremity and typically have a lower degree of contamination and typically exhibit an improved ability to fight infection. Furthermore, this was a retrospective study without control or comparison groups [2].

In contrast to the ED setting, there have been several studies investigating the amount of irrigation required during formal debridement in the operating theater. However, the recommended volumes of irrigation in theater were always described arbitrarily in several published studies [3–6].

Gustilo et al. described the use of 10-14 liters of irrigation intraoperatively [4,5]. Anglen recommended the use of irrigation bags, which are readily available in three liters, for intraoperative irrigation (three liters for Gustilo type I, six liters for Gustilo type II and nine liters for Gustilo type III) without citing any supporting data [6].

Although several studies have investigated open fracture management, the volume of fluid irrigation utilized in them was based on the same rule of "3, 6 and 9" and none of them addressed the amount of irrigation used in the ED [7–11].

After review of the literature, there has been only one clinical study related to the volume of irrigation for open fractures in the ED and this was limited to open fractures in the hand and fingers. Nevertheless, in the ED setting, irrigation of the wound with enough volume until all grossly visible contamination and debris is removed seems, at the very least, an appropriate amount.

QUESTION 3: What is the recommended volume and composition of irrigating fluid in the operating room for open fractures and post-traumatic wounds?

RECOMMENDATION: Irrigation in open fractures should be performed with normal saline and gravity flow irrigation. 3-9L is a reasonable volume to use. Bactericidal washes with agents like chlorhexidine or povidone-iodine have not been adequately studied in orthopaedic trauma patients, but basic science studies raise concern that they may damage tissues.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Irrigation is a central tenet in open fracture management, reducing bacterial concentrations and removing foreign materials from traumatic wounds. The goal in these injuries is to reduce the known risks of infection, wound healing problems and nonunion. Irrigation requires a balance between removing contaminants and causing further trauma to tissues or spreading contamination. Questions about irrigation include the ideal volume, fluid composition and pressure of irrigation solutions.

The one identified randomized controlled trial comparing different osmolality irrigating agents of distilled or boiled water and isotonic saline did not have clearly-defined outcome measures or follow-up criteria, but reported a 25.5% overall infection rate without any significant difference between the irrigation solutions [1].

Regarding antiseptic solutions, the majority of data is in animal or cadaveric models. This literature raises concerns about host cell toxicity that could affect wound healing or fracture union when utilizing agents such as ethanol, povidone-iodine, bacitracin solution, chlorhexidine solution, or hydrogen peroxide [2–8]. Additionally, there is some data showing that bacterial count reductions from soap or antiseptic solutions may be temporary and followed by disproportionate rebound at later time points, which has led some authors to recommend saline irrigation [9]. Regarding human clinical data, there is one moderate-quality randomized controlled study comparing bacitracin to castile soap for the irrigation of 458 open fractures in 400 patients. Minimum follow-up was 180 days, with an overall infection rate of 15.3%, a wound complication rate of 6.8% and a nonunion or delayed union rate of 23.9%. They reported similar infection and nonunion rates but increased wound-healing complications in the bacitracin group [10].

Volume

We were unable to identify any studies that specifically compared the volume of irrigation in a controlled manner in open or traumatic wounds. However, most studies used a minimum of 3L of irrigation and increased this amount by 3L per additional Gustilo type (3L for Gustilo type I, 6L for Gustilo type 2, 9L for Gustilo type 3), as in the 400-patient RCT by Anglen et al. [10].

Pressure

Pulsatile lavage theoretically improves dislodgement by cyclically compressing tissues then allowing them to decompress and recoil, freeing bacteria and foreign material. Pulsatile lavage has a proven clinical track record in reducing debris and bacterial counts in traumatic wounds when compared to gravity or bulb syringe irrigation [11–14]. However, basic science studies have raised concerns that pressurized lavage may be detrimental to bone healing and may seed bacteria distant to sites of initial contamination [5,15–18].

In the largest study on wound irrigation in open fractures, the Fluid Lavage of Open Wounds (FLOW) Group conducted an international, 41-center, blinded, randomized controlled trial assigning 2,447 patients with open extremity fractures to irrigation with high (> 20 psi), low (5-10 psi) or very low (1-2 psi) pressure with either castile soap or normal saline [19]. Irrigation for Gustilo type I injuries was 3L and types II and IIIA/B were 6L, with type IIIC injuries excluded from the trial. Of note, this study had the additional benefit of relatively standardized care in the pre-, intra- and post-op settings regarding components such as prophylactic antibiotic type and timing, skin prep solutions, debridement, skeletal stabilization and wound management including closures, dressings and soft tissue coverage. They reported no statistically significant difference between the pressure groups for the primary endpoint of reoperation within 12 months for promotion of wound or bone healing or for a wound infection. This study reported an overall 6.8% infection rate, 3.6% wound complication rate and 6.8% nonunion rate at 12 months.

The overall reoperation rate for infection, wound or bone healing was 13.2%. There was a significantly lower reoperation rate in the saline group than the castile soap group (14.8% vs. 11.6%, hazard ratio 1.32, 95% confidence interval 1.06–1.66, p = 0.01). Neither pressure nor solution composition led to significant difference in the secondary outcomes of non-operatively managed infection, wound-healing problem or bone-healing problem. In the subgroup analyses, there was a trend toward superiority without reaching statistical significance for very low-pressure irrigation in tibial fractures [19].

QUESTION 4: What is the most appropriate management of early (prior to complete wound healing) infection after fracture fixation with stable fixation?

RECOMMENDATION: The most acceptable treatment strategy for trauma patients with early postoperative infection is to perform proper irrigation and debridement, administer intravenous (IV) followed by oral antibiotic therapy and retain stable hardware in place.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

The definition and classification of early infection after isolated fracture fixation (IFF) is a dilemma among orthopaedic trauma surgeons [1–3]. However, the clinical picture of early infection including local (e.g., hematoma, wound discharge and dehiscence, erythema around the incision) and systemic (e.g., fever, lethargy) symptoms are usually diagnostic in most situations. Although it is not clear whether the biofilm formation process during the early postoperative infection period will be stopped or delayed with appropriate treatment, the goal of the treatment at this stage is to control the infection until complete union is achieved at the fracture site. After fracture healing, removal of the implant will help to eradicate the infection. This strategy is different than the typical treatment of a periprosthetic joint infection (PJI) in which the infected implant is replaced in two stages (spacer and then re-implantation of the total joint arthroplasty). The treatment strategy might be different based on the evaluation of the local and systemic clinical picture in each individual case. However, based on the available literature and our experience, it is possible to suggest some general recommendations.

The most significant difference between IFF and PJI is the higher chance of infection control and eradication by removing the implant during or after bone healing is complete for IFF cases. Therefore, especially in early postoperative IFF cases, infection control is the main goal of medical and surgical treatment [4,5]. The treatment options are described as ranging from simple antibiotic suppression to removal of the current implant to multiple stage revisions [4,5]. The most reasonable treatment strategy that is applicable to most cases is performing irrigation and debridement, retaining the stable fixation, and administering IV antibiotic therapy [4–7]. More than one washout or debridement may be necessary to clean the operative site and optimize wound healing [8,9]. Local antibiotic delivery (e.g., bead pouch, calcium sulfate beads) may be helpful. Proper soft-tissue coverage and aggressive debridement are the main principals of the surgical part of the treatment. Early flap coverage is critical if hardware is exposed [10].

The use of negative-pressure wound therapy coupled with continuous instillation of an antibiotic solution containing gentamicin and chymotrypsin has also been shown to facilitate a healthy wound bed for healing while maintaining fracture fixation with or without additional surgery for secondary closure [11]. In patients who are at high risk for wound healing problems, incisional negative-pressure therapy may be helpful following the washout [12,13].

Empiric systemic antibiotic therapy followed by organism susceptibility-based therapy should be started after early irrigation and debridement. Systemic antibiotic therapy can be curative or suppressive [14]. After a period of two weeks, IV antibiotic therapy can be replaced by appropriate oral therapy based on the available culture results [15–17]. It is recommended to continue the oral therapy for an additional four to six weeks to prevent chronic

osteomyelitis and suppress the infection [14,18]. In some situations, one may consider long-term oral suppressive therapy until union is achieved before considering implant removal.

Surgical intervention usually is needed to control the IFF. The main challenge is whether or not to remove any stable implants. Removal of stable internal fixation during the early postoperative period, especially in complex situations, will compromise bone healing. It has been shown in multiple studies that there is a strong correlation between fracture stability and bone healing [19–21]. Theoretically, proper irrigation and debridement in the early stage of the IFF can reduce the bacterial load and lower the speed of biofilm formation, which will also help the fracture consolidation process.

During initial debridement, local delivery of the antibiotic at the fracture site can be implemented by using absorbable or non-absorbable materials. However, there is no strong evidence to support the advantage of using local delivery systems as well as systemic antibiotic therapy. Aminoglycosides and vancomycin are the most commonly used antibiotics for local delivery [22]. Industrial premixed or hand-mixed polymethylmethacrylate bone cements are widely used to deliver antibiotics to the infection site by different techniques including molded beads or coated intramedullary nails [23]. The need for removal and less optimal release of the incorporated antibiotics are the main disadvantages of the antibiotic-loaded cements [24]. Good primary results are reported for resorbable materials such as calcium sulfate [25–28]. However, there is no high-quality study to show the superiority of these materials to the antibiotic -loaded cements in terms of clinical outcomes. Recently, hydrogels were introduced as an attractive and effective delivery vehicle for traumatic wounds with reasonable outcomes, which needs to be validated by further high-quality studies [22,29,30].

Although irrigation, debridement, and retention of the stable fixation device were reported as a successful treatment strategy for early IFF in a few studies, there is no strong evidence to support this treatment protocol, especially in the very early stage (before wound healing). Berkes et al. [6] reported a 71% fracture union rate in 121 patients with early postoperative (within 6 weeks) IFF after treatment with irrigation and debridement, implant retention, and culture-specific antibiotic suppression. Open fractures and the presence of an intramedullary nail were reported as the positive predictors of treatment failure. Rightmire et al. [7] reported a similar rate of bone healing (68%) with the same strategy for treatment of early IFF (within 16 weeks). However, there is no available evidence for the appropriate treatment of the infection in the postoperative period before wound healing occurs (two weeks).

Based on the available evidence and our experience, the most acceptable treatment strategy in trauma patients with early postoperative infection is proper debridement, antibiotic therapy (IV followed by oral) and retention of the stable hardware already in place.

QUESTION 5: What is the most appropriate management of early (before complete wound healing) infection after fracture fixation with unstable fixation?

RECOMMENDATION: The most appropriate management of early (prior to complete healing) infection after fracture fixation with unstable fixation consists of surgical debridement with removal of fixation implants, fracture stabilization, antibiotic therapy and soft tissue coverage, if needed.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Infection after fracture fixation is a serious complication in orthopaedic trauma surgery, as it may eventually lead to devastating outcomes such as amputation [1]. In contrast with periprosthetic joint infections, literature regarding this condition is still limited considering the number of patients affected [1,2]. Nonetheless, in order to unify the evidence available, major efforts have been made to accurately define "infection after fracture fixation" [3]. The current definition includes a classification according to the onset of symptoms and early infection is considered that which occurs during the first two weeks after the index procedure. [2,4]. For this recommendation, this definition will be maintained.

Several systematic and non-systematic reviews gathered the existing evidence for infection associated with orthopaedic implants. All conclude that antibiotic suppression therapy and surgical debridement with implant retention is a suitable option for the treatment of early infection after fracture fixation when fracture healing has not yet been achieved, but the construct is stable [1,2,4–8]. Therefore, to date, this continues to be the standard of care for early infections. Likewise, the outcomes presented by Trebse et al. [9], Rightmire et al. [10] and Berkes et al. [11] all showed favorable results for this method of management, with success rates ranging from 68% to 92%. However, the quality of evidence of these studies is low.

The question remains whether implant retention is still a viable option for unstable fixation. Metsemakers et al. [2], in their more recent review, suggest that implant exchange or removal should be considered in early infections when intramedullary devices are used, unstable fixation exists or insufficient fracture reduction is present. These recommendations are based on the works by Trampuz et al. [4], Kleber et al. [12] and Rightmare et al. [10]. Moreover, several animal studies have addressed the importance of fracture stability in implant-related infections [13–15]. When fixation is unstable, implant retention is not an option. The existing implants do not provide enough stability at the fracture site, which will impair fracture healing as well as facilitate persistence of infection.

Even though both Rightmire et al. [16] and Berkes et al. [17] performed a multivariate analysis, neither of them reported "unstable fixation" as a predictor of treatment failure [10,11]. The quality of the presented evidence is low and the methodology used might not have been appropriate to conclude that implants must be removed under these conditions.

After performing a systematic search of the literature, no conclusive evidence on the management of early infection with unstable fixation was identified. Therefore, our recommendation is based on clinical experience, established knowledge of implant-related infection [18] and the management of infected non-unions [19,20]. Furthermore, adequate coverage of the fracture site with a well-vascularized soft tissue envelope facilitates both control of infection and fracture healing. Therefore, in the case of soft tissue defects or scarred soft tissues with poor vascularity, a soft tissue reconstructive procedure is usually necessary [21,22].

QUESTION 6: What is the appropriate timing of conversion to internal fixation (in-fix) following external fixation (ex-fix)? How is this altered by pin site infection?

RECOMMENDATION: Timing of conversion should be based on patient characteristics including concurrent injuries and premorbid health and function, as well as injury features and location. One-stage conversion appears to have similar or even lower infection rates compared to two-stage conversion. In the absence of pin site infection, early conversion is preferred.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

American development of external fixation is credited to Parkhill in 1897 and European development to Lambotte in 1900 [1]. Ex-fix is often used in polytraumatized patients as part of a damage-control orthopaedic approach, in injuries with extensive soft tissue compromise, or when appropriate personnel or resources for in-fix are not readily available [2,3]. It is applicable to periarticular fractures, long bone fractures and articular dislocations, making it an essential component of contemporary orthopaedic traumatology.

Recent literature review using the databases Embase, Scopus, Google Scholar and PubMed was performed with the search terms "internal fixation," "external fixation," "timing" and "conversion" in multiple combinations. Articles were reviewed for relevance and studies were then assessed for quality and assigned a level of evidence.

Following ex-fix, conversion to in-fix can have multiple benefits for patients. A prospective comparison of 39 patients with open lower leg fractures treated with primary ex-fix with randomized conversion to intramedullary nailing (IMN) or to cast immobilization showed significantly shorter mean time to union (26.3 vs. 35.4 weeks), higher overall consolidation rates (94% vs. 64%), and better knee and ankle range of motion (ROM) for IMN [4]. Regarding timing of conversion from external to internal fixation (which includes plate/screw constructs and intramedullary nail constructs), major questions within the field are as follows: (1) Should conversion be performed in one procedure (acute) or in two (staged)? (2) Does time in ex-fix affect outcomes following conversion? (3) Do pin site infections increase the risk of deep infection following in-fix? (4) Does timing of soft tissue coverage affect outcomes following conversion? [2].

Regarding staging, theoretically staged conversion should allow time for pin site granulation and decrease infection rates. Therefore, some authors recommend delayed internal fixation until pin sites heal closed [5]. However, data from level IV studies do not support this. Horst et al. reported on two protocols, one for immediate conversion and one for staged conversion from external to internal fixation. They included local excision of skin-pin interfaces and curettage of soft tissues around pin track sites. For immediate conversion, pin sites were disinfected and covered prior to re-prepping of the surgical field. Pin sites were left covered until all in-fix wounds were closed, and then pin sites were left open with antibacterial dressings. For staged conversion, ex-fix was exchanged for a cast and any required soft tissue coverage was performed prior to in-fix. After institution of this algorithm utilizing the immediate conversion protocol, they observed a decrease in time to conversion (mean 6.8 > 5.0 days), hospital length of stay (mean 25.4 > 16.3 days) and complication rate (21% > 8.3%) [6].

Monni et al. performed a retrospective review of 18 patients (24 limbs) undergoing conversion from external to internal fixation for traumatic bone defects or congenital deformities. Indications for conversion included patient dissatisfaction with ex-fix, pin track sepsis, persistent non-union or refracture. In-fix consisted of IMN or plate and screw constructs. Conversion was performed acutely (19 limbs) or staged (5 limbs). The outcome was considered excellent if patients were full weightbearing, pain free, had a mechanically well-aligned limb and did not need further surgery within the follow-up period. The outcome was considered good if patients required subsequent surgery to achieve union and the outcome was considered poor if an irreversible complication occurred. The acute group had 16 excellent and 1 good outcomes (89.4%), with 2 (10.6%) poor outcomes resulting in amputation, both after acute conversion to IMN for infected tibial nonunion. The delayed group had four (80%) excellent and one (20%) good outcomes. They cautioned against using IMNs in patients with a diagnosis of an actively septic nonunion and reported that conversion to in-fix generally produces good to excellent results [7]. Bandhari et al. found that shorter intervals between ex-fix removal and IMN, for planned or salvage procedures, correlated with reduced infection, but do comment that in level IV studies this may represent confounding [8].

Farrell et al. reported on ex-fix with one-stage conversion to in-fix for nine calcaneus fractures. Ex-fix was applied within 24-48 hours and converted to open reduction and internal fixation (ORIF) through a sinus tarsi approach at an average of 4.8 days from ex-fix. There were no pin tract infections, deep infections or wound healing complications [9]. Natoli et al. reported on 16 complex distal radius fractures, 11 of which were open, and treated with an ex-fix and converted to ORIF at a mean of 8.5 days. One patient developed deep infection, and they did not report a relationship with open fractures, time to conversion of < or > 7 days, or ex-fix pins overlapping the definitive fixation [10]. Shah et al. reported on pilon and tibial plateau fractures treated with ex-fix converted to ORIF excluding cases with evidence of overt pin site infection. They demonstrated a 24% rate of deep

infection when definitive fixation overlapped pin sites, compared to 10% when it did not; a statistically significant increase [11].

Roussignol et al. performed a retrospective review of 55 patients treated with ex-fix and secondary IMN after traumatic tibial shaft fractures (16 closed, 39 open). Of note, they also excluded patients with external fixator pin site infections. They analyzed time to IMN (mean 9 +/-9.6 weeks), acute or delayed exchange (23 acute vs. 32 staged, mean 12-day interval), culture results of reaming products, post-IMN infection and time to union. There were four septic complications and one aseptic nonunion requiring re-nailing. Acute versus delayed IMN did not correlate with increased infection risk, with only open fracture grade correlating with infection risk, and the union rate was 96%. Based on these results, they therefore recommend acute (one-stage) exchange of ex-fix for IMN [12]. Bhandari et al. performed a literature review on ex-fix conversion to IMN in tibia and femur fractures, including one level II study and the remainder level IV studies. They looked at studies with planned conversion from ex-fix to IMN, and those where IMN was used to salvage failed treatment with ex-fix. In 6 studies totaling 185 patients for planned conversion for femur fracture, with a mean 10 days ex-fix and 1 day interval to IMN, the infection rate was 2.6%. For tibias, 9 studies on planned conversion (n = 268) averaged 8.6% infection and 92% union, with shorter ex-fix time (< 28 days) correlating with an 83% reduction in the risk of infection compared to > 28 days [8].

Regarding time in ex-fix, Monni et al. reported a mean ex-fix time of 185 days (range 61-370), with poor outcomes correlating with longer time [7]. Bhandari et al. performed a meta-analysis assessing when to perform conversion, with deep infection rates 83% lower when IMN was performed within 28 days compared to after 28 days [8]. These studies both suggest earlier conversion is preferable. However, Yokoyama et al. performed multivariate analysis of 42 cases of secondary IMN after open lower leg fracture treated with initial ex-fix, with 7 (16.7%) developing deep infection, and found only time to skin coverage, with a threshold of 1 week, was significantly correlated with deep infection. They did not find a relationship between infection and the duration of ex-fix (</= or > 3 weeks), the interval between ex-fix removal and IMN (</= or > 2 weeks), or the existence of superficial infection or pin tract infection [13]. Similarly, Roussignol et al. did not find a correlation between infection risk and time in ex-fix before IMN [7].

While most studies have excluded patients with active pin site infections, Yokoyama et al. did not find a relationship between superficial infection or pin tract infection and rates of deep infection after IMN [13].

Regarding timing of soft tissue coverage, the previously cited Yokoyama et al. noted restoration of soft tissue coverage within one week correlated with a decreased risk of infection [13]. Outside of external to internal fixation conversion, other literature has used the threshold of five days from initial injury to wound closure before rates of wound healing complications and infections increase [9]. Most orthopaedic literature supports earlier soft tissue coverage in open fractures as protective against infection, irrespective of fixation type [14].

QUESTION 7: What are the alternatives to segmental resection in septic non-union?

RECOMMENDATION: Surgical alternatives to segmental resection include bone grafting, unroofing, decortication, distraction osteogenesis or intramedullary reaming to address the site of osteomyelitis. All dead bone and soft tissue should be removed.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 91%, Disagree: 0%, Abstain: 9% (Super Majority, Strong Consensus)

RATIONALE

Operative debridement of necrotic tissue has been a surgical principle of infection treatment for centuries. Reports from the 1960s demonstrated that it is sometimes possible to heal a fracture nonunion with bone grafting and stabilization without disruption

of the non-united bone site [1]. However, failures were common and continued infection was an expected outcome. In 1984, Cierny et al. published a classification of osteomyelitis and described both an anatomic description of the site of infection and a description of the host with recommendations for debridement strategy [2]. The fundamental principle is debridement of all dead and infected bone in the same manner that a malignancy would be treated with a marginal excision.

Cierny's guidelines are that infection involving only the medullary canal can be potentially treated with reaming or a reamer-irrigator aspirator (RIA) to achieve adequate debridement. More localized infection can be treated with unroofing or decortication of the bone segments. However, diffuse infection over a segment of the bone requires segmental resection to achieve complete debridement of all dead bone. In addition to these recommendations, segmental resection may be preferred when distraction osteogenesis is planned for the bone defect reconstruction.

Resection of the non-union followed by a two-stage procedure with the use of a spacer and bone graft/allograft, shortening, intercalary implant or bone transport after six weeks is unquestionably the gold standard of treatment [3–7]. Intravenous antibiotics are also very important in the treatment of infected non-united bone and can be used alone but functional blood supply is necessary for successful results [6,8]. A local muscle flap or pediculated bone graft with or without free flap can be used to gain infection control but these do not usually prevent infected bone resection [9–14].

In most cases, external fixation with Ilizarov´s method or unilateral fixators can be used successfully in combination with local application of antibiotic or bone-inducing agents [15–22]. Some authors describe the use of local cement application for several weeks before local bone grafting without segmental resection [23–27]. In some cases of septic non-union, the application of bone marrow with stem cells or human bone morphogenetic protein (hBMP) was used with good results [28–32]. Antibiotic-coated plates are also used in some cases [33,34]. In the ankle region specifically, arthrodesis can be an option to achieve septic union in infected cases by stabilizing the non-union site [35]and persistent drainage is only an option,albeit poor, in elderly patients [36]. It has been shown both in vitro and in vivo that cement coated implants or temporary cemented rods or spacers can be used without the need for segmental resection in septic non-union after nailing or with intramedullary infection [37–54]. There are indications where sufficient infection control for bone healing can be reached with stable implants.

Alternative strategies are the use of bioactive glass for osseous induction as an allograft or as carrier for antibiotics which showed promising results in infected bones – but blinded and randomized trials are still missing [6,55–61]. The loading of nano-particles with antibiotics, microspheres, polymer-lipids (and bacteriophages) is another very promising method, as is the induced membrane technique using beta-tricalcium phosphate [62]. The advantages of antibiotic release-control could be an important step in the treatment of infected bone non-union in the future, but Level I studies are missing here [63–81]. Furthermore, there are no comparative studies examining relative success of different debridement strategies.

Segmental resection is performed in cases of septic non-union with undersupplied, chronic infected and atrophic "dead" bone. In minor cases, segmental resection could be avoided by using other treatment options. Debridement strategies guided by Cierny's recommendations, including segmental resection when required, are recommended [82–85].

Eradication of infection is the main goal of the treatment and segmental resection can sometimes by the most useful method to accomplish this. Alternative treatments to segmental resection have not yet been determined to be as successful as the standard treatment. As of now, there is not enough evidence supporting a change of the accepted standard of care in septic non-union but some promising approaches are being explored.

QUESTION 8: What is the optimal management (Masquelet technique, bone transport) of postinfective bone defects in different long bones (tibia, femur, humerus, etc.)? How does this vary by type of defect (conical vs. cylindrical)?

RECOMMENDATION: The type of defect (cylindrical vs. conical) was not determined to be relevant to the treatment method. Instead, optimal management of partial vs. full segmental defects is relevant. Each long bone requires different preferred methods of stabilization.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 95%, Disagree: 0%, Abstain: 5% (Unanimous, Strongest Consensus)

RATIONALE

The most complete systematic review was published in 2017 by Kadhim et al. [1] This review reported that in 96 femoral segmental bone defects, monolateral external fixation with bone transport was 99.7% effective for union and 94.7% successful for function compared with 88.9% and 57.6% for circular external fixation, respectively. Supplemental internal fixation in this study decreased the external fixation time. Yin et al. [2] reported their series of 38 femoral fractures with infected segmental bone defects (average size, 6.5 cm) that were treated with application of monolateral external fixation and bone transport. The mean external fixation index was 1.5 months/cm (range, 1.3–1.7 months/cm). Only five femurs required docking site bone grafting. Good/excellent results (evaluated using the Association for the Study and Application of the Methods of Ilizarov (ASAMI) Classification) for bone were 87.3% and good/excellent results for functional outcome were 79%. Multiple other studies have reported similar results with monolateral bone transport but with fewer numbers of patients [3–5]. Docking site bone grafting is not always necessary except in longer transports that result in fibrous tissue at the docking site with some atrophy of the transported bone end [4,5]. Monolateral bone transport is much less technically challenging than classic Ilizarov transport in the femur; therefore, this technique is more accessible to a larger number of surgeons.

Few studies document the success of vascularized fibular bone grafts (VFBGs) in post-infectious segmental bone defects [6–8]. Minami et al. [6] reported on 23 post-infectious femoral segmental bone defects treated with VFBG. Twenty of 23 patients achieved primary bone union; however, 2 patients had recurrent infections. Both of these patients underwent VFBG less than one month following resection for osteomyelitis; therefore, the authors' recommendation [6] was to delay the VFBG for longer than one month after the resection and until serologic infection markers returned to normal. Gao-Hong et al. [7] reported using VFBG for infected femoral segmental defects ranging from 6 to 18 cm with primary bone healing in 10 of 12 patients. Additional surgery improved the healing rate to 100% (12/12) with eradication of infection in all cases. According to Enneking scoring, excellent/good results were observed in 11 of 12 patients [7]. Han et al. [9] reported on VFBG for defects following infection with a primary union rate of only 48%. With additional procedures, this rate increased to 77% (46/60). The literature has small numbers of VFBG reconstruction for post-infectious defects of the femur with results that are not comparable to the success of bone transport. Song et al. [10] studied post-infectious femoral defects (> 8 cm) and compared 20 cases treated with internal bone transport to 17 cases treated with VFBG. The bone transport cases had 65% excellent/good result compared to 35% in the VFBG cases. The complication rate is high regarding donor site morbidity [11] and fibular stress fractures, which range between 15% and 32% [12,13]. The VFBG technique is technically demanding, requires microsurgical skills, and is not readily accessible to many orthopaedic surgeons.

No large series has been reported of the induced membrane technique for post-infectious defects of the femur. There are 3 series with 19, [14] 13, [15] and 13 cases [16]. Wu et al. [14] reported 19 cases with an average 5.5-cm defect (range, 2–10.9 cm). The first stage was external fixation and cement spacer placement. The second stage of treatment was combined internal fixation with autograft/auto-allograft mix into the induced membrane. All femurs united and were free of infection [14]. Yu et al. [15] reported 13 cases of septic femoral bone defects averaging 9.8 cm (range, 5–16 cm). The first stage fixation was an antibiotic-coated locked plate and the second stage fixation was an intramedullary nail. The reported union rate was 100%, and 92% of patients were infection free for at least one year [15]. Tong et al. [16] also reported 13 cases of femoral posttraumatic osteomyelitis. They compared bone transport to the induced membrane (IM) technique and found that the IM technique had better results in the

femoral cases, especially the periarticular bone defects [16]. These publications [14–16] have promise but are retrospective with only small numbers.

The publications regarding the IM technique have many variations including timing to second stage, the presence of antibiotics in the spacer and the type of fixation used for stage one and two [17]. The important unifying principles are radical debridement of infection, proper installation of the cement spacer overlapping the normal bone ends, waiting for the soft-tissue envelope to heal with normal serologic markers and stable fixation during the interval prior to the second stage [18]. Infection eradication is the most essential element in achieving success. This technique therefore requires a minimum of two surgical procedures. The largest series published to date is by Karger et al. [19] with 84 cases. Fifty percent of the cases were for infection, the average number of operations to achieve union was 6.11, and 57% of the defects were larger than 5 cm. An abnormal soft-tissue envelope needs to be addressed with soft-tissue transfer (adjacent or free) in order to promote good soft-tissue healing and a stable wound bed for the second stage [20,21]. The Masquelet technique holds promise but the surgeon should proceed with caution as several surgical procedures may be needed to achieve the desired result. In theory, any size defect can be treated and there is no prolonged external fixation time as in bone transport. The time to achieve union with this technique appears to be independent of the length of the defect; however, a 2 cm defect and a 15 cm defect both may take as long as 10 months to heal [19]. The recommendation is moderate because of the lack of large prospective series reports in the literature and the number of average surgical procedures needed to achieve success.

Kadhim et al. [1] recently published a systematic review of nonunion with segmental bone defects that included 334 tibiae. The most successful method of reconstruction with respect to bone union and function was circular external fixation combined with internal fixation (either bridge plating or intramedullary nail). This provided a 99.8% success rate with respect to both union and function. Papakostidis et al. [22] also demonstrated in their systematic review that distraction osteogenesis with the Ilizarov method statistically significantly reduced the risk of infection in previously infected defects. They also showed that the risk of refracture following removal of external fixation was higher when tibial defects were larger than 8 cm [22].

Rohilla et al. [23] published a randomized prospective study with 70 patients comparing ring fixators and monolateral fixators for infected tibial defects. They concluded that for defects greater than 6 cm, a ring fixator had superior results [23]. They attributed this finding to the larger numbers of patients in the monolateral group who had residual problems with greater than 6 cm of lengthening such as infection, deformity and shortening. Also, the monolateral group had statistically significantly more problems with deep pin tract infections than the ring fixator group [23].

Many other studies have also documented the success of circular external fixation and bone transport in the tibia. Yin et al. [2] in 2014 reported 66 patients with infected segmental tibial bone defects with an average size of 6.3 cm (range, 3–13 cm). All tibiae were treated with bone transport with circular external fixation and united without recurrence of infection. Fifty-nine patients had excellent/good results according to the ASAMI classification [2]. Docking site bone graft was performed in only six patients. The most common complication was pin tract infection in 40 patients with 38 of the 40 being treated with orally-administered antibiotics and pin care. The mean external fixation index was 1.38 months/cm (range, 1.15–1.58 months/cm). Only two patients had refracture after frame removal, which was treated with reapplication of the external fixator [2]. Peng et al. [24] reported 58 cases of tibial infected nonunion with an average defect of 9.2 cm (range, 6–15 cm) that were treated with bone transport with circular external fixation. Fifty-three patients had excellent/good results using the Paley grade and 36 excellent/good functional results. There were no refractures and only one recurrent infection [24].

Hexapod external fixators have also been used for bone transport using the method of Ilzarov. Napora et al. [25] reported 75 infected segmental bone defects of the tibia (average size, 5.4 cm) treated with a hexapod external fixator. Seventy of 75 patients had eradication of infection and full union. Thirty-two patients required a free flap by plastic surgery, and 36 patients had adjunctive stabilization with either an intramedullary nail or plate fixation at or following removal. Many other articles detail the success of circular external fixation and bone transport in the tibia [26–31].

Another treatment option is acute shortening with lengthening. One paper [32] with a total of 42 patients reported similar results when comparing acute shortening with lengthening to bone transport. The only difference was a statistically significantly smaller number of major and minor complications per patient. This technique is helpful only when the fibula is broken and the soft-tissue envelope is amenable to shortening using a transverse incision. Excessive shortening greater than 4 cm can lead to ischemia of the leg due to arterial kinking and the authors highlight the need to monitor the vascular status of the limb whenever shortening is employed.

Some literature has been published on the IM or Masquelet technique for infected tibial segmental bone defects. There is some variability with respect to the technique among the papers, and some critical differences may lead to poorer outcomes using the technique. Tong et al. [16] compared the Masquelet technique for infected segmental tibial bone defects to Ilizarov bone transport. The average bone defect size was 6.8 cm (range, 2.7–15.7 cm). Twenty-six patients had tibial defects with 13 patients in each group. The IM group was treated with external fixation for stage two as well. In this series, there was no statistically significant difference between bone results in the 13 bone transport cases and 13 IM cases. It is interesting to note, however, that a recurrent infection in the IM group was treated with bone transport to union. Functional results were better in the IM group because of the statistically significantly smaller external fixation time (10.2 months [range, 8–14 months] versus 17.2 months [range, 11–24 months]). Seventeen excellent/good functional results were observed for the Masquelet technique versus nine excellent/good functional results for bone transport.

Karger et al. [19] in 2012 published the largest series of the IM technique for segmental bone defects. They included a total of 84 cases that included 61 tibial defects. Of the 61 tibial cases, there was an average time to union of 14.6 months with an average of 11.5 interventions. Full weight bearing was started at a mean of 17.4 months after the initial treatment of the bone defect. Eight tibial cases failed, and six required amputation. Qiu et al. [20] reported 40 tibial posttraumatic osteomyelitis defects. There were 2 groups: a cement bead group (18 patients) and a cement-spacer group (22 patients). The volumes of the bone defects for each group were 32.4 cm^3 (range, 15–40 cm^3) and 40.4 cm^3 (range, 20–70 cm^3), respectively. Nineteen of these bone voids were partial defects. The bone healing time was 8.5 months in the spacer group and 7.5 months in the bead group. Infection control was also similar in the two groups: 88.9% for the bead and 90.9% for the spacer groups. Eighteen patients had soft-tissue coverage by plastic surgery. Stable fixation was obtained at the initial débridement with either internal or external fixation and there were no amputations [20]. This study demonstrates that the IM technique can be successful for small defects.

Sadek et al. [33] also demonstrated that the IM technique for tibial defects smaller than 6 cm was comparable to Ilizarov bone transport in a small, case-matched series totaling 30 patients (14 and 16 patients per group). Giannoudis et al. [34] reported 43 long bones

that were treated with the IM technique; however, only 11 were tibial defects with an average defect size of 4 cm (range, 2–7.5 cm). All bones united with one complication of recurrent infection treated with repeat debridement. This study highlights one of the problems with the IM technique papers in that many different anatomic regions are considered together. Morelli et al. [35] performed a systematic review of the IM technique with 17 papers that met the inclusion criteria; however, only 10 of these papers reported individual patient data for a total of 137 cases. Persistent infection or nonunion was present in 18% of cases requiring repeat surgical interventions. There has been much enthusiasm for this technique because it is technically less challenging for the surgeon and it appeals to patients because it does not have prolonged external fixation time. This technique, however, has pitfalls with many variations of the technique being reported with variable outcomes. Surgeons should proceed with caution as recurrent infection and nonunion may require repeat operations and ultimately increase total treatment time.

Now turning attention to the upper extremity, Adani et al. [36] published a series of 13 cases of VFBG for humeral segmental defects, of which 8 were infected. The average defect in these cases was 12.3 cm (range, 10–16 cm). Five of eight patients required additional procedures (e.g., bone grafting, plate revision, new VFBG). The repeat VFBG was secondary to a vascular pedicle failure. According to Tang criteria, functional recovery was excellent/good in all eight cases and radiographically excellent/good results were seen in five of eight cases.

One series in the literature has 12 pediatric patients with humeral osteomyelitis with an average defect size of 5.5 cm [37]. Initial treatment consisted of excision of infected bone, autograft nonvascularized fibular strut and plate fixation, and limb shortening. Ten of 12 patients healed after the initial surgery. One patient required additional bone grafting. One patient developed a recurrent infection and required re-debridement and re-bone grafting with ultimate success. The average residual shortening of the limb was 3.5 cm (range, 2–6 cm).

Rafiq Barawi [37] published the results of 10 patients with infected humeral defects averaging 6 cm (range, 3–9 cm) treated with Ilizarov bone transport. All 10 cases had Paley class excellent/good results radiographically and functionally at latest follow-up, with an average external fixation index of 1.16 months/cm. Liu et al. [38] reported 11 patients with humeral osteomyelitis and segmental defects. The average gap was 1.9 cm (range, 1–2.7 cm) with an average humeral shortening of 5.6 cm (range, 3.5–8.0 cm). The average humeral lengthening was 9.5 cm (range, 5.5–13.4 cm). The average external fixation index was 1.16 months/cm (range, 1–1.35 month/cm). Ten of 11 patients healed, and all patients were eradicated of infection. All patients had excellent/good results. No docking site bone graft was performed in any of the cases. The most common complication was pin tract infection. Two pins were exchanged in two patients for loosening.

Adani et al. [39] published a series of 12 cases using VFBG in the forearm where 10 of the 12 cases had osteomyelitis. The average defect was 8.4 cm (range, 6–13 cm). Two cases required additional bone grafting and both of these cases had a history of osteomyelitis. A third case was considered a failure secondary to thrombosis of the artery of the VFBG. Therefore, 9 of 10 cases of forearm osteomyelitis healed with 2 requiring additional bone graft procedures. The average time to healing was 4.8 months (range, 2.5–8 months). Internal fixation was used for 9 of 10 cases. Seven of nine patients had excellent/good results clinically and eight of nine patients had excellent/good results radiographically.

The alternative treatment is the IM technique as applied in the forearm. Prasarn et al. [40] published a series of 15 cases of infected forearm nonunion treated with debridement and nonvascularized iliac crest bone graft with open wound healing by secondary intention. All bones united and were free of infection with an average time to union of 13.2 weeks (range, 10–15 weeks). The average defect size was 2.1 cm (range, 1–7 cm). Allende [41] in 2010 published 20 cases with healing of infection and nonunion at an average of 5 months. Luo et al. [42] published a series of 7 forearm infections with an average defect size of 5.8 cm (range, 4–8 cm) treated with the IM technique. The average number of procedures to achieve success in these patients was 3.43 (range, 2–5 procedures). The authors emphasize that a number of debridements may be required to achieve an uninfected environment. Serial debridement's were also determined by Masquelet [18] to be critical to achieve an uninfected wound bed and ultimate success with the technique. One patient required repeat bone grafting [42]. At latest follow-up averaging 86.7 months (range, 41–150 months), all patients were healed, uninfected and had statistically significant improvement in functional scores.

Two studies reported the results of bone transport in forearm nonunions. Zhang et al. [43] published a series of 16 cases with an average defect of 3.8 cm (range, 2.2–7.5 cm) with a mean external fixation index of 1.6 months/cm (range, 1.14–2.0 months/cm). All patients healed, and there was no recurrence of infection. No docking site was bone grafted. Liu et al. [44] reported on 21 patients with infected forearm nonunion who underwent treatment with monolateral fixation. The average defect was 3.1 cm (range, 1.8–4.6 cm), and the external fixation index was 1.4 months/cm. Four patients had docking site bone grafting. Three patients had regenerate bone grafting, and 3 patients had recurrent infection requiring repeat debridement. Mean follow-up was 77.5 months. All forearms healed and were free of infection.

QUESTION 9: What is the optimum waiting time for bone grafting in staged management of septic nonunion?

RECOMMENDATION: The interval between the first and second stages should be dependent upon infection control and the status of the local soft tissue of the individual patient, rather than any specific time. Therefore, the precise time is unknown. The current recommendations are that if conditions are favorable, the second stage can be performed between 6 and 12 weeks after the first stage. This recommendation may not apply to the Masquelet technique.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Successful treatment of infected long bone nonunions remains a great challenge for the orthopaedic trauma and limb reconstruction surgeon. They are frequently associated with bone and soft tissue loss, failed internal fixation, broken implants, poor vascularity, drainage from sinuses, osteopenia, osteomyelitis, adjacent joint stiffness, deformities, length discrepancies, prior surgery and polymicrobial infection with resistant organisms [1–4]. Available evidence on the operative management of infected long bone nonunions indicates that staged reconstruction (incorporating debridement, antibiotic beads, soft tissue coverage and provisional stabilization, followed by delayed osseous reconstruction and definitive stabilization [3–6]) can achieve union in 93–100% of cases. With expert care under staged protocols by surgeons specializing in musculoskeletal sepsis, persistence of infection is present in only 2-9% of cases [5,6],

TABLE 1. Studies before 2000

Author	Year	Type of Study	Number of Patients	N Septic Nonunion	Mean Follow-up, Months (Range)	Location	Timing of Bone Grafting (Weeks)	Recurrence of Infection	Union
Green [10]	1983	Case series, retrospective	15	15	42 (24-78)	Tibia, femur, ulna	**4**	0%	87%
Esterhai [11]	1990	Case series, retrospective	42	36	Not specified	Tibia	**1**	31%	72%
Ueng [12]	1994	Case series, retrospective	13	8	37 (24-54)	Tibia	**2-4**	0%	100%
Patzakis [13]	1995	Case series, retrospective	32	32	28 (12-49)	Tibia	**8**	0%	91%
Emani [14]	1995	Case series, retrospective	37	37	24	Tibia	**2.1**	0%	100%
Cove [15]	1997	Case series, retrospective	44	12	28 (24-108)	Femur	**Min 2**	0%	92%
Chen [16]	1997	Case series, retrospective	14	14	73 (29-108)	Humerus	**6**	0%	93%
Ueng [17]	1999	Case series, retrospective	15	11	58 (40-76)	Femur	**2-6**	18%	100%

which is significantly better that one-stage strategies or two-stage strategies without local antibiotic depots using polymethyl methacrylate (PMMA) beads [2–4].

Although bone grafting is widely used for the treatment of infected nonunions, there is little evidence on the optimum timing of its use in the staged management of septic nonunion. A search in the Ovid Database (including Embase and Medline) did not identify any studies focusing on the optimum timing of bone grafting. The current evidence is based on studies that report outcomes on the management of infected nonunions. The most commonly reported prerequisite for bone grafting is complete eradication of infection. This is confirmed either clinically (absence of systemic signs such as fever or local signs such as dry healed wounds), by laboratory tests (normalization of inflammatory markers) [7,8] or by biopsies [9].

There has been only one randomized control study on the management of infected nonunion [8]. This study compared the use of antibiotic-impregnated autologous cancellous bone graft with pure autologous cancellous bone graft in the management of infected nonunions. The timing of bone grafting depended on whether muscle transfer was required. Bone grafting was performed after five weeks on average (range two to seven weeks) from the last debridement and application of PMMA if muscle transfer was not required and on an average 10 weeks (range 8 to 12 weeks) if muscle transfer was required. There were no results reported specifically for the two groups with different timing of bone grafting. This study showed that antibiotic-impregnated bone graft was associated with lower rates of recurrent infections than pure bone graft. The rest of the published studies were case-series reporting outcomes on the staged management of infected nonunions.

Interestingly, there has been a change in the timing of bone grafting for the staged management of infected nonunions over the course of the past several decades. Prior to 2000, the mean time of bone grafting was four weeks following the first-stage procedure [10–17] (Table 1). Furthermore, in only two [13,16] out of the eight published studies, bone grafting was carried out later than four weeks from the first-stage procedure. On the contrary, after 2000 the mean time between the first and second stages was 7.9 weeks and in no study was bone graft implanted earlier than four weeks from the first stage [7–9,18–35] (Table 2). This could be partially explained by increasing popularity of the induced membrane technique. The most recent case series use the principles of this technique for the effective eradication of infection and reconstruction of bone defects. The time interval between the two stages of the procedure is essential not only for the eradication of the infection but also for the maturation of the induced membrane. This may be another reason towards the shift of longer waiting times between the two stages.

In summary, even though there are no studies assessing the optimum timing of bone grafting in the management of septic nonunion, current case series recommend an interval of 7-8 weeks while most studies range between 6-12 weeks following debridement.

3.5. TREATMENT: MANAGEMENT OF HARDWARE

Author: J. Tracy Watson

QUESTION 1: When should hardware be removed when treating surgical site infection (SSI) in orthopaedic trauma?

RECOMMENDATION: The decision to retain or remove hardware differs by clinical scenario and must take into account extent of the infection and stability of the hardware and fracture.

A methodical approach that addresses the pathogen, host factors and bony and soft tissue deficiencies is required, and includes thorough debridement, dead-space management and soft tissue and bony reconstruction using the established principles of the reconstruction ladder.

Acute or Subacute Infection with Stable Hardware and Fixation

When dealing with orthopaedic implant-related infections, the most common recommendation of nonsurgical consultants is to remove all hardware, obtain deep cultures and administer antibiotics. This is unfortunately only partially correct. Cultures are helpful, and antibiotics are essential, but the removal of stable, functioning hardware in the setting of an acutely infected fracture

should generally be resisted. Although it is well-known that the presence of inanimate material surfaces increases the risk of infection, lowers the inoculum necessary to cause infection and reduces the chances of successful treatment, longstanding clinical experience has demonstrated that skeletal stability reduces the infection rate [2,3]. This reduction is supported by the results of animal studies [4,5]. The mechanism by which instability promotes infection is not clear, but may have to do with interference with revascularization of injured tissues, ongoing tissue damage, altered fluid-flow behavior locally or increased micro-dead space. Although instability seems to interfere with the resolution of infection, the presence of infection does not necessarily prohibit bone healing. A logical strategy is to maintain stable internal fixation, which will facilitate union, and plan for hardware removal later if infection persists after the bone is healed.

For the treatment of acutely infected fractures, Berkes et al. reported a 72% rate of fracture union and resolution of infection utilizing a standardized protocol of operative debridement, retention of *stable* fracture hardware and culture-specific intravenous antibiotics. Factors that were predictors of treatment failure included the injury being an open fracture ($p = 0.03$), the presence of an intramedullary nail ($p = 0.01$), a high association with smoking and any infection with Pseudomonas species or other gram-negative organisms [6].

Other authors have also identified factors that contribute to the successful salvage of acutely infected fractures. These include the maintenance of stable hardware and time of surgery to infection diagnosis less than two weeks [7].

Another factor for successful salvage is the ability to achieve a thorough debridement of the fracture construct. If a collection of pus exists around an implant or under a flap or incision, it must be thoroughly drained. Incisions made for irrigation and debridement of infection should rarely be closed and should be placed carefully to avoid exposing hardware, bone, tendon or neurovascular structures. If these are unavoidably exposed, consideration should be given to flap coverage of the wound. The ability to achieve competent wound closure is another predictor of successful salvage. Vacuum-assisted closure (VAC, (Kinetic Concepts, Inc.)) dressing can be used temporarily in the short-term while awaiting definitive coverage.

As mentioned previously, culture specific antibiotic treatment should be standard when treating acutely infected stably fixed fractures. Furthermore, consideration to adding rifampin to culture proven Staphylococcal infections should be strongly considered. A randomized controlled trial to evaluate the utility of adding rifampin to Staphylococcal infection associated with stable orthopaedic implants demonstrated a 100% cure rate in the group treated with ciprofloxacin-rifampin compared to the 58% cure rate in the group receiving ciprofloxacin-placebo [8]. All patients underwent an initial debridement followed by a two-week course of an intravenous antibiotic regimen of flucloxacillin or vancomycin with rifampin or placebo. Long-term therapy was either ciprofloxacin-rifampin or ciprofloxacin-placebo.

In a study by Rightmire, et al. [9] outcomes in patients with acute infections after fracture repair managed with retained hardware were reviewed. They evaluated the effectiveness of irrigation, debridement and antibiotic suppression in the setting of retained hardware. A successful outcome was defined as a patient obtaining fracture union with the original hardware in place. A failure was defined as a patient requiring hardware removal before fracture union [9]. There was only 68% success with an average of 120 days until fracture healing, and 36% of these patients went on to present with reinfection. The majority of the infected fractures that failed debridement and antibiotics with retained hardware failed within three months.

It is important to consider all information when deciding to retain or remove hardware in treatment of these infections, including the specific characteristics of the fracture, the type of fixation, the virulence of the pathogen and physiology and function of the patient.

Acute or Subacute Infection with Unstable Fracture, Fixation and/or Hardware

The presence of excessive motion, the displacement of hardware on radiographs or the visualization of radiolucencies around screws, rods or fixator pins denotes an unstable situation. This instability compromises the ability to overcome infection and to heal the fracture. Bacteria that are attached to surfaces such as metallic fixation devices or dead bone become resistant to the action of antibiotics through the production of biofilm. In the face of unstable hardware or fracture malalignment, the hardware should be removed.

Animal studies with an infected fracture model document the detrimental effects of fracture instability. The infection rates at two weeks post-infection were lower in internally-fixed fractures with stable fixation compared to unstable fractures with loose pins. Stability lowers the incidence of *S. aureus* infection and other gram-positive organisms. However, gram-negative infections were less likely to be successfully suppressed in the internally fixed group and the infection could only be eradicated if the hardware was removed [5].

Friedrich et al. noted similar findings in infected fractures with retained hardware [4] and infection developed in 45% of unstable fractures. However, infection did NOT occur after rigid fixation. With rigid fixation, no significant difference in the time to bony union was noted between the infected versus uninfected fractures. It is important to note that fracture instability, particularly with loss of fixation, may also be a confounded clinical scenario, demonstrating a more widespread infection that prevents callus formation and leads to bone loss and loss of fixation.

Chronic Osteomyelitis

Debridement

Chronic infection after injury is largely a surgical disease and is rarely successfully treated by antibiotics alone. Surgical debridement should be undertaken by experienced surgeons using particular techniques that adhere to established principles, many originally described by Cierny [10–14]. If infection persists after fracture union, hardware must be removed and avascular bone and soft tissue debrided. In general, previous incisions should be used, and all necrotic soft tissue should be removed [10–14]. In the case of structures important to function and with questionable viability (tendons and ligaments), a staged approach can be taken. Care should be taken to not strip viable periosteum from bone. Sclerotic or sequestered bone should be removed until all the remaining bone appears healthy and bleeds well. A high-speed burr is a gentle way to accomplish removal of necrotic infected bone [10–14].

Local Antibiotic Delivery

To prepare defects for grafting or coverage following debridement, antibiotic-impregnated polymethyl methacrylate (PMMA) beads, rods or blocks are often placed to deliver a high concentration of antibiotics locally while avoiding systemic toxicity. Antibiotic elutes from the PMMA by diffusion from the surface. Although most of the drug elutes in the first 24 hours, therapeutic levels of drugs have been detected in some cases for as long as 90 days. Tissue concentrations may be higher and persist longer than those seen in

elution experiments. Although many surgeons believe that antibiotic beads used to treat osteomyelitis should be removed, one retrospective study suggested that improved outcomes followed leaving the beads in situ [14].

After removal of an intramedullary rod, placement of antibiotic beads offers no mechanical support. Beads within the intramedullary canal must be removed within 10 to 14 days or subsequent removal may be extremely difficult [15,16]. Antibiotic cement rods can be custom-made at the time of surgery using varying chest tubes as molds [16]. Following thorough medullary canal debridement, the antibiotic rod is inserted and does provide some mechanical stability**.** If additional debridements are necessary, the antibiotic rod is exchanged. At the time of definitive closure, the antibiotic rod is left intact in the canal, and the wound is closed directly over it. After a six- to eight-week interval, the rod can be removed and bony reconstruction can be undertaken.

QUESTION 2: Which surgical treatment (plate, nail or external fixator) for open tibial shaft fractures results in lower rate of infection?

RECOMMENDATION: There is little to no difference in terms of infection rates for Gustilo-Anderson types I–II treated by either circular external fixator, unreamed intramedullary nail or reamed intramedullary nail. For Gustilo-Anderson IIIA-B fractures, circular external fixation appears to provide the lowest infection rates when compared to all other fixation methods.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

A systematic review was undertaken on all English language articles on infection rates following the treatment of open tibial shaft fractures. The literature search included Google Scholar and the Medline, Embase and Cochrane databases. The search terms included open tibia, tibia fracture and tibial diaphysis with the Boolean terms 'AND' and 'OR.' All abstracts were reviewed, and the full articles were obtained for all potentially suitable articles.

Review articles and those that included peri-articular open fractures and pediatric fractures were excluded. A total of 54 articles were excluded for review. Information regarding Gustilo-Anderson types and infection rates were extracted from all included articles (Table 1).

Statistical analysis revealed that across all Gustilo-Anderson types, circular external fixation and intramedullary nailing have significantly lower infection rates compared to plate fixation or monolateral external fixation. Across all types, there is minimal to no difference between circular external fixation and unreamed intramedullary nailing or reamed intramedullary nailing (Table 2).

When Gustilo-Anderson type IIIB injuries are isolated, circular external fixation appears to have a significantly lower risk of risk of infection when compared to reamed and undreamed intramedullary nail fixation (Table 4).

In conclusion, from the available published English literature on infections rates for open tibial shaft fractures treated by various different fixation methods, plate fixation and monolateral external fixation have significantly higher infection rates when compared to circular external fixation or intramedullary nailing. There appears to be little to no difference for Gustilo-Anderson types I – IIIA treated by either circular external fixator, unreamed intramedullary nail or reamed intramedullary nail. For Gustilo-Anderson type IIIB fractures, circular external fixation appears to provide the lowest infection rates when compared to all other fixation methods.

QUESTION 3: When performing intramedullary (IM) fixation, what is the evidence regarding reaming versus non-reaming and the association with infection?

RECOMMENDATION: Based on the current evidence, there is no difference in infection rates following IM fixation of long bone fractures using a reamed or non-reamed technique.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Using an IM fixation technique has become the accepted standard in treating long bone fractures. Tibial fractures are the most common type of long bone fracture encountered and therefore are the most studied in the current literature [1,2]. Evidence has supported that IM nailing is superior to external fixation with regards to patient outcomes [3–5]; however, there has not been a consensus with regard to reamed versus non-reamed IM nailing technique.

Classically, the arguments against the use of reaming point to the risk of fat embolization from the marrow-generated from the increased intramedullary pressure created during the technique, and development of acute respiratory distress syndrome (ARDS) [6,7]. Also, long bone fractures are often the result of high-energy injuries and are accompanied with varying degrees of periosteal stripping [4]. This inherent soft tissue damage can predispose patients to complications, such as infections, especially in open fractures. In addition to the soft tissue compromise secondary to the trauma, reaming has also been shown to disrupt endosteal blood flow and to cause thermal necrosis of the bone [4,7]. This is thought to have the potential to further increase the risk of infection due to added insult to the soft tissue [4]. To avoid such adverse effects and complications, a non-reamed IM nailing technique was developed.

Despite the described adverse results of reaming, current literature has not convincingly proven an association between reaming and infection rates. Finkemeier et al. conducted a prospective, randomized study analyzing 94 patients with closed and open tibial fractures treated with either reamed or non-reamed IM nailing [8]. There was no statistically significant difference in the infection rate between the two study groups. When comparing infection rates of only closed fractures treated with reamed and non-reamed techniques (4% vs. 4%, p = 0.945), no statistical difference was observed [8]. Open fractures also had no significant difference in infection rates when treated with the studied techniques (5% reamed vs. 4% non-reamed, p = 0.851) [8]. Similarly, Blachut et al. conducted a prospective study of 141 fractures randomized into reamed and non-reamed groups and found no increased rate of infection [9]. Both of these studies noted that their smaller sample sizes could limit the quality of the evidence they presented [8,9].

A much larger prospective, blinded randomized trial was conducted by the Study to Prospectively Evaluate Reamed Intramedullary Nails in Patients with Tibial Fractures (SPRINT) investigators [1]. This study randomized 1,319 tibial shaft fractures into reamed or non-reamed cohorts and did not allow re-operations for nonunion to occur before six months in order to effectively evaluate the outcomes of the techniques [1]. The results of their study found a statistical difference in the relative risk (RR) of a primary event when a reamed technique was used in a closed tibial fracture (RR = 0.67 confidence interval (CI), 0.47-0.96, p = 0.03) [1]. The RR of an infection in a closed fracture, however was not statistically significant when comparing the reamed and unreamed groups (RR = 1.37, CI 0.48-3.93, p = 0.56) [1]. The same was seen in open fractures when comparing the infection rates of the two techniques (RR = 1.27, CI 0.67-2.40, p = 0.46) [1]. The SPRINT trial was unable to draw any conclusions about risks of infections between reamed and non-reamed techniques due to disparity between the study groups. The authors of the study noted that there was potential bias in their study, for their surgeons had more expertise with the reamed technique [1]. This could have biased their data against the non-reamed group.

A systematic review and meta-analysis of a pooled group of 646 patients conducted by Bhandari et al. found a RR of reamed versus nonreamed IM nails of 0.98 (CI 0.21-4.76, p = 0.86) for rate of infection [10]. They did note trends in favor of reamed IM nailing with closed fractures and nonreamed IM nails in open fractures. Due to the lack of significance in the results, however, they were unable to draw definitive conclusions pertaining to infection rates between the studied techniques [10]. Foote et al. conducted a network meta-analysis to analyze all treatment options for open tibial shaft fractures [2]. Similar to Bhandari et al., they were unable to find a difference between reamed and non-reamed IM techniques (direct evidence non-reamed vs. reamed odds ratio (OR) = 0.74, CI 0.45-1.24) [2].

A third systematic review was also unable to establish a statistically significant difference between infection rates when using a reamed technique as opposed to a non-reamed technique (RR = 1.19, CI 0.71-2.00) of the 1,545 patients included in this analysis [11]. Of note, the Duan et al. systematic review was heavily dominated by the inclusion of the SPRINT trial which contributed the majority of the patients to the overall analysis and was cited as a potential weakness of their study [11].

Despite concern of an increased rate of infection when a reamed technique is used for IM nailing, current evidence has been unable to elucidate a difference between reamed and non-reamed IM nails in this regard. There are several studies addressing the issue, however smaller sample sizes in all of these studies prevents one from drawing a definitive conclusion [8,9,11]. In addition, the current literature focuses primarily on outcomes aside from infection. The high-energy nature of fractures treated with these techniques as well as the open/closed nature of the injury can also be confounding factors limiting many authors' ability to draw definitive conclusions. Therefore, there is no conclusive evidence linking

IM reaming with increased rates of infection when compared to non-reamed techniques.

QUESTION 4: Are antibiotic coated rods (ACRs) and antibiotic coated plates (ACPs) an acceptable alternative to cement only implants?

RECOMMENDATION: Antibiotic-loaded polymethyl methacrylate (AL-PMMA) spacers can be considered an established treatment concept for local antibiotic delivery in osteomyelitis and implant-associated infections.

ACRs and ACPs can also be of value in specific indications, mainly infected non-unions, in order to address both local delivery of antibiotics and biomechanically stable fixation of the non-union site to allow for possible spontaneous bone consolidation.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 91%, Disagree: 5%, Abstain: 4% (Super Majority, Strong Consensus)

RATIONALE

Biomechanically stable ACRs, such as antibiotic coated interlocking nails, and ACPs exhibit the advantage of additionally providing sufficient biomechanical stability to allow for bone healing in infected non-unions compared to antibiotic delivery only by biomechanically unstable drug carriers. There are only a few limited case series available on biomechanically stable ACRs [1–4] and ACPs with the study of Conway et al. being the largest with 110 patients on locked ACRs that were retrospectively analyzed [1]. A good overall clinical outcome could be accomplished with an overall limb salvage rate of 95% (105/110 patients) in infected non-union and infected arthrodesis.

For ACPs, there is only one case report and one case series with four patients all of whom showed healing of the formerly infected fracture by the use of the ACPs [5,6].

QUESTION 5: What is the ideal composition of antibiotic-impregnated intramedullary (IM) nails?

RECOMMENDATION: The ideal composition of antibiotic-impregnated IM nails is unknown. The core should consist of a rigid structure such as an Ender's IM nail, Ilizarov threaded rods, IM locked nails, carbon fiber nails or sectioned pins or guidewires. We recommend at least 2 grams of vancomycin and 2.4 grams of an aminoglycoside be added to each pack (40 grams) of polymethyl methacrylate cement. If a specific micro-organism is isolated, targeted antibiotic therapy should be included.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 86%, Disagree: 9%, Abstain: 5% (Super Majority, Strong Consensus)

RATIONALE

Infection following IM nailing of long bone fractures is a recognized complication that can be difficult to treat successfully [1]. The incidence is variable depending on the degree of soft tissue and bone compromise, ranging from 1.8% in closed fractures and Gustilo type I open fractures up to 12.5% in type IIIb open fractures [2]. Almost half of these are caused by multiple organisms. Zych et al. [2] reported that 56% of these infections were caused by a single organism, predominantly caused by *Staphylococcus aureus* (50%) followed by *Bacteroides fragilis* (3%) and *Streptococcus pyogenes* (3%). The remaining cases were caused by a combination of these and *Enterobacter cloacae, Serratia marcescens, Proteus mirabilis, Escherichia coli,* and *Pseudomona aeruginosa*. In all infections, *Staphylococcus aureus* was present in 64% of cases.

Antibiotic cement-impregnated IM nails (ACIMNs) have been described as a treatment option for this complication. These are designed to provide stability while delivering local antibiotics. Initially described by Paley and Herzenberg in nine cases, they used a chest tube as a mold and a guidewire as a core, covered with antibiotic-loaded bone cement [3]. The treatment strategy with the use of ACIMNs is generally performed in a two-stage fashion. An initial debridement and implantation is followed by subsequent removal with or without definitive hardware exchange [4–6].

The greatest disparity among ACIMNs is the element used as the core. Investigators have reported different components including Ender's IM nails, Ilizarov threaded rods, IM locked nails, interlocked carbon fiber nails, sectioned pins or guidewires [7]. ACIMNs act as antibiotic-loaded cement spacers, similar to those used in two-stage exchange arthroplasty for periprosthetic joint infection treatment, [8] with additional temporary fracture or bone stabilization [9].

Regarding construct rigidity, the core diameter is the most important factor. It is important to note that these are significantly weaker than conventional IM nails given the antibiotic coating. Thus, a balance between the core diameter and planned diameter of ACIMN should be carefully calculated. In a mechanical study by Marmor et al. [10] different core diameters were evaluated. A 5.8-mm-core diameter cement rod bending stiffness was reportedly higher, 4.96 ± 0.67 N/m2, than a 3-mm-core, 3.07 ± 0.28 N/m2, ($p = 0.0039$). The second important factor is the thickness of the cement mantle, which is currently unknown given different variables of the cement composition. Vaishya et al. [11] suggest a cement mantle thickness of 2 to 3 mm without clear evidence supporting this statement. The reduction in the volume of cement coating raises concerns regarding the effectiveness of antibiotic delivery. However, the elution properties of the impregnated antibiotics have been shown to depend on the surface area and porosity of the mixture, not the thickness. In a study by Karek et al. [12], they demonstrated that a thin mantle would potentially allow for higher elution of antibiotics caused possibly by the result of a cooler exothermic reaction.

Different techniques of ACIMN fabrication have been described [3,7,13]. The use of a mold and manual fabrication has been commonplace for the past two decades. These have different advantages and disadvantages such as fabrication speed and the morphology of the implant. Molds such as chest tubes seem to be the best option as they generate a smooth implant that facilitates their later removal. Kim et al. [5] evaluated the time required to peel the chest tube off the ACIIN using different cement-cooling techniques. They found that the fastest and most effective way is cooling the cement in cold water and pre-lubricating the chest tube with mineral oil. They also recommend the use of 3-mm beaded IM guidewire that is cut to a length 3 cm longer than the length of the tube allowing creation of a hook or loop for subsequent removal.

Broad-spectrum antibiotics are routinely used as infections are generally poly-microbial. The most commonly used antibiotics are vancomycin, tobramycin, gentamycin or a mixture of these [14]. Antibiotics must have certain properties in order not to compromise their efficacy. Anagnostakos et al. [15] identified these properties as availability in powder form, wide spectrum coverage, bactericidal activity, high elution properties, thermo-stable and hypoallergenic [16]. Targeted therapy if a micro-organism has been isolated is desired if certain criteria are met.

Reported success rates range with the use of ACIMNs range from 69% to 100% with the use of different constructs and similar antibiotic compositions [4,6,17–21]. We, therefore, consider the ideal composition currently unknown. We do consider, with the available literature descriptions, that there are several considerations that need to be employed in the construction of these devices. The core should consist of a rigid structure with the largest diameter possible to increase rigidity while not compromising cement mantle stability. The system should have an extraction element for subsequent removal. Based on recommended antibiotic concentrations for spacers, most authors use a mixture of at least 2 gm of vancomycin and 2.4 gm of an aminoglycoside in 40 gm of bone cement. Prior research has shown that this is the minimum concentration needed for attaining long-lasting antibiotic elution in the surrounding space [22]. There is little evidence of systemic toxicity with high antibiotic concentrations in the cement mixture used to coat nails, but a dosage safety range has not been established. If a specific micro-organism is isolated, targeted antibiotic therapy should also be considered.

QUESTION 6: What is the ideal composition of antibiotic impregnated (ABI) spacers/beads in post-traumatic infections? Is preoperative microbial identification necessary?

RECOMMENDATION: There is currently limited evidence with regards to the ideal composition of ABI polymethyl methacrylate (PMMA) spacers or beads in post-traumatic infections and the need for preoperative identification of the causative organism. Available data suggests that PMMA spacers, empirically impregnated with at least 2 gm of vancomycin per 40 mg of PMMA (with or without gentamycin), may result in quiescence of infection in a high percentage of cases with an acceptable associated rate of bony union. Preoperative microbial identification is of unclear utility.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 95%, Disagree: 0%, Abstain: 5% (Unanimous, Strongest Consensus)

RATIONALE

The challenge of achieving adequate local tissue antibiotic concentrations with systemic antibiotics has prompted the addition of local antibiotic therapy in the majority of bone infection protocols. The use of ABI PMMA beads is well established in the treatment of chronic osteomyelitis. Klemm reported a cure rate of over 90% in 405 cases of chronic sequestrating osteomyelitis with the use of gentamycin-impregnated PMMA bead chains [1]. Notably, the beads were pre-manufactured with gentamycin and Klemm found no change in the gentamycin resistance profile over a seven-year period. The use of local antibiotic therapy has also been advocated in the post-traumatic setting. Numerous review articles advocate for the use of ABI PMMA or other forms of local adjuvant antibiotic therapy in the setting of septic non-union or post-traumatic infections [2–5]. Interestingly a recent comparison of the outcomes of treatment with ABI beads versus spacers revealed no difference in the rate of infection control, time to union or complication rate with either configuration [6].

The induced membrane ("Masquelet") technique has gained popularity in the management of post-infective bone defects [7]. The procedure involves the placement of a PMMA spacer in the defect, followed by a subsequent second-stage bone grafting into the resulting induced membrane [8]. Originally the procedure was described using bone cement without antibiotics. Masquelet reasoned that the inclusion of antibiotics may increase the risk of resistance to the offending organisms and that it changed the biological characteristics of the induced membrane [9]. This concern was validated, in an animal model by Nau et al., who demonstrated variations in the nature of the induced membrane with different types of bone cement and supplemental antibiotics [10]. Notably, Palacos[å] with gentamycin still resulted in a positive rate in cell growth. However, in clinical studies involving post-traumatic (not post-infective) bone defects the concerns regarding inhibition of bone healing were not realized, with reported union rates of 82% (in cylindrical defects) to 100% (in conical defects) with the use of ABI spacers [11,12].

While the original technique involved PMMA without antibiotics, several other authors have utilized the potential advantage of local antibiotic elution during the construction of the spacer [13–18]. If the data from the meta-analysis by Morelli et al. is scrutinized it appears that there may well be a therapeutic advantage with the addition of antibiotics in terms of infection control. When evalu-

ating the studies that included only post-infective bone defects it is noteworthy that there was recurrence of infection in two out of 17 cases in which PMMA without antibiotics was used, [19] compared to no recurrence in 58 cases in which ABI spacers were used [5–8]. Furthermore, the addition of antibiotics may not necessarily result in inferior bony healing with union reported in 100% of the cases in which ABI PMMA spacers were used. The heterogeneity of these studies, however, prevents drawing firm conclusions in this regard. The successful use of ABI spacers has, however, recently been corroborated in a larger series (involving 22 cases of acute post-traumatic defects and 21 post-infective defects) by Giannoudis et al., who reported an overall union rate of 93% and only one case of recurrent infection at 2-years follow-up.

Despite the promising results that have been achieved with ABI PMMA, the optimal composition of the spacers remains to be determined. Rathbone et al. examined the effect of 21 different antibiotics on the viability and osteogenic activity of osteoblasts. Amikacin, tobramycin and vancomycin were found to be the least cytotoxic agents [20]. No well-designed comparative clinical studies to asses different spacer compositions have yet been performed in the post-infective setting. The choice of antibiotic appears to be empirical in most studies and none have reported it is necessary to preoperatively determine the causative organism. The most popular composition appears to be 2 to 4 gm of vancomycin added to 40 gm of PMMA with or without gentamycin (or tobramycin) [5,6,10–12].

QUESTION 7: Should antibiotic cement rods (ACRs) be left permanently in situ?

RECOMMENDATION: If the ACR is used as a temporary non-locked implant for infection control, it should be removed and replaced by a biomechanically stable construct (e.g., locked intramedullary nail). If the ACR is used as a locked implant for both local delivery of antibiotics and provision of stable biomechanical conditions for consolidation of the non-union site, it can be left in place.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 70%, Disagree: 30%, Abstain: 0% (Super Majority, Weak Consensus)

RATIONALE

ACRs can be used for two different indications.

1. ACRs are used as non-locked temporary implants for the local delivery of antibiotics into the intramedullary canal to eradicate the infection. In cases with stable bone conditions, e.g., chronic osteomyelitis in long bones, missing rotational stability of the ACR is not relevant, whereas in infected non-unions with unstable bone conditions, the ACR is removed after infection control and replaced by a biomechanically stable implant, in most cases by a standard interlocking nail in a subsequent revision procedure.

For this indication, only technical notes, case reports and small case series with a maximum of 19 cases in one study exist [1–8]. In the 18-patient case series by Qiang et al., the mean indwelling time of the ACR was 57 days, ranging from 35 to 123 days [6]. Sancineto et al. published 19 cases with removal of the ACR between 6 and 76 weeks after surgery [7]. Badhra and Roberts reported some difficulties in

the removal of antibiotic nails that have been implanted for more than two months. They found that proximal incarceration of the nail requiring debridement of bone could occur and might need to be addressed using osteotomes [1]. Paley and Herzenberg also retained their cement-coated rods for up to 753 days without any major complication except rod fracture in one patient [5].

There is one study by Selhi et al. in which in some cases of unlocked ACRs were used for infected non-unions and these were retained for a longer period of time in order to achieve bone healing despite the absence of rotational stability. ACRs were kept for a period ranging from 6 weeks to 22 months with an average of 10.6 months [8]. These rods were usually retained until bony union occurred or secondary procedures like external fixation, intramedullary nailing, and/or bone grafting was performed.

2. ACRs can also be used as locked ACR with adequate biomechanical stability in infected long bone non-unions for both local delivery of antibiotics and provision of stable biomechanical conditions for consolidation of the non-union site [9–11]. For this indication, several retrospective case series (with a maximum of 110 cases in one study) exist. Good clinical outcomes with a healed uninfected bone in 105/110 patients (95%) was demonstrated [9]. Removal of the ACR was not reported in the articles and one can assume that the implants were left in place in order to not weaken the bone.

3.6. TREATMENT: WOUND COVERAGE

Authors: Konstantinos Malizos, Martin McNally, Efstratios Athanaselis, James Chan

QUESTION 1: Is there evidence to support one type of flap coverage over another (e.g., muscle over fasciocutaneous flap) after open tibial fractures?

RECOMMENDATION: Different types of flap coverage after open tibial fractures have essentially equivalent and comparable outcomes in terms of flap survival, bone healing, stress fracture, infection, chronic osteomyelitis and donor site morbidity. Local flaps should be considered in low energy trauma, when available. The type of flap should be tailored based on the extent and the depth of the soft tissue defect and the location of the fracture. In high energy fractures of the tibia, muscle flaps may offer a more reliable reconstruction with fewer flap failures and fewer reoperation rates.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 95%, Disagree: 5%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

Multidisciplinary management of severe open tibial fractures with radical debridement, skeletal fixation and early stable coverage is essential for infection prevention and high-quality, cost-efficient trauma care [1]. The Gustilo-Andersen grading system of open tibial fractures is a significant prognostic factor of infectious complications and non-unions [2]. Open fractures of the tibia have a high incidence of infection and malunion [3,4]. Wound coverage does not only prevent wound desiccation and infection, but also contributes to fracture repair by serving as a local source of stem or osteoprogenitor cells, growth factors and vascular supply [5,6].

There is a growing body of evidence demonstrating that the biological characteristics of the tissues in a flap can significantly influence fracture healing, and the rate of delayed union or non-union. Timing of soft tissue coverage is also a critical determinant of the length of in-hospital stay and most of the early postoperative complications and outcomes [7]. Early coverage has been associated with higher union rates and lower complication and infection rates compared to those reconstructed after 5-7 days [2,5,7–9]. Furthermore, early reconstruction improves flap survival, as microsurgical free flap integration becomes more challenging with a delay due to an increased pro-thrombotic environment, tissue edema and the increasingly friable vessels. Only those patients presenting to facilities with an actual dedicated ortho-plastic trauma service are likely to receive definitive treatment of a severe open tibia fracture with tissue loss within the established parameters of good practice [7]. "Fix and flap" is being recommended for specialist hospitals where the expertise is available. Antibiotic bead pouches to decrease infection rates have been advocated when there is segmental tissue loss,

gross contamination or established infection as pre-flap tissue infection seems to be an independent predictor of adverse flap and skeletal reconstruction outcomes [10,11].

Fasciocutaneous flaps may be better suited and superior compared to muscle flaps for coverage of the shallow defects at the rapidly uniting metaphyseal fractures around the ankle, particularly with no massive bone or soft tissue loss [6,10,12]. They are easier to monitor postoperatively and tend to have better venous and lymphatic drainage with less acute swelling and better aesthetic appearance [10,13]. Additionally, they become potentially sensate and pedicle-independent from secondary neuro-angiogenesis permitting low-risk flap elevation for subsequent procedures [10,14,15].

Human stromal cells derived from muscle exhibit a significantly greater potential for osteogenesis than those from fasciocutaneous tissue, including both skin and adipose tissue, and are equivalent to those from bone marrow [2,16,17]. Muscle flaps covered with skin grafts in direct apposition with diaphyseal fractures help to obliterate the dead space, reducing potential complications associated with hematoma formation. They may be superior in eliminating bacteria from the wound bed [5] and enhancing healing, but remain pedicle-dependent and difficult to elevate for secondary procedures such as bone grafting. Muscle-only flaps may also have a false high rate of re-operation due to difficult postoperative monitoring. An alternative with the biological benefits of both is a chimeric flap, such as the free anterolateral thigh flap, which includes a segment of *vastus lateralis* [11,14]. Muscle flaps with a cutaneous skin paddle are easier to monitor and thus have a higher salvage rate. Rotational flaps with fasciocutaneous tissue and muscle for proximal defects have shown significantly more complications including infection, necrosis or partial flap loss, compared to free muscle flaps in patients with the most severe grade of osseous injury (44% compared to 23%), and are more likely to require operative re-intervention [6,18].

The selection of proper free flaps for the appropriate defects is also of critical importance, as those with extensive tridimensional tissue loss need free muscle flaps because they conform better to such complex defects [5]. However, free fasciocutaneous flaps are reliable and effective for covering the less three-dimensional distal third and ankle open tibial fractures and can better tolerate the subsequent secondary surgical procedures [11,14,15,19]. It is also important to not underestimate donor-site morbidities [6,13,18]. Surgeon experience and familiarity with the flap should also be an important factor in flap selection. However, the dilemma of choosing between muscle and fasciocutaneous flaps is less relevant than identifying the patient that is at risk of a poor outcome and managing them appropriately [12–14,16]. Finally, there seem to be few significant differences between muscle and fasciocutaneous flaps or between local and free flaps [12,15,19–21]. Although not identified in the Search criteria the following article was felt to be important enough to be included, as it is a recent retrospective study of 39 patients with Gustillo IIIB tibial fractures, muscle flaps may be preferred over fasciocutaneous flaps in these patients. Radiographic assessment of these patients revealed a significantly greater percentage of patients treated with a muscle flap reaching fracture union by six months. There was no statistical difference between muscle and fasciocutaneous flaps at 3 or 12 months though [22]. However, local flaps are preferable in low velocity trauma and free tissue transfer appears to have advantages in high-velocity injuries [10,16].

Published studies on reconstruction of traumatic defects of the tibia are mostly retrospective studies with small, heterogeneous patient cohorts. A few of these compare muscle with fasciocutaneous flaps, but include a wide variety of patients and clinical indications, without sufficient details on the criteria used to select coverage of open tibial fractures [11,12,21]. The outcome measures between studies are different, as not all studies report time to union of the fracture, rates of deep infection or even flap survival. Overall, there is little difference in the clinical outcome with regard to infection rates, wound healing or fracture union, but no study is sufficiently powered to answer these questions. These parameters preclude meaningful systematic review or meta-analysis that can provide standardized guidance for the use of different flap options in the management of open fractures of the tibia [1,11].

To improve the patient's outcome, appropriate international consensus guidelines are required, breaking down also the length of hospital stay and the overall healthcare cost [1].

At this point, based on our understanding of the literature, we believe that different types of flap coverage after open tibial fractures have essentially equivalent and comparable outcomes in terms of flap survival, bone healing, stress fracture, infection, chronic osteomyelitis and donor site morbidity, with the timing of the coverage also being crucial. The type of flap should be based on the extent and the depth of the soft tissue defect, location of the fracture and surgeon experience.

More specifically, if we have to categorize them:

1. In low-energy trauma, local muscle or fasciocutaneous flaps should be considered the reconstruction of choice, if they are available.
2. In high-energy injuries such as open fractures of the tibia, muscle flaps may offer a more reliable reconstruction with fewer flap failures and lower reoperation rates. Free muscle flaps are more advantageous for the reconstruction of tridimensional bone and soft-tissue defects.
3. In patients with simple defects around the distal tibial or ankle, fasciocutaneous flaps may offer a better option.

Author: David Lowenberg

QUESTION 2: What is the appropriate timing for flap coverage of open fractures and traumatic wound defects?

RECOMMENDATION: The optimal time for wound coverage ultimately reflects when the wound has been appropriately cleaned and converted to a "living wound." Early flap coverage is preferred, ideally within 3-7 days, when patient and wound are suitable.

LEVEL OF EVIDENCE: Strong

DELEGATE VOTE: Agree: 95%, Disagree: 5%, Abstain: 0% (Unanimous, Strongest Consensus)

RATIONALE

The timing of soft tissue coverage has long been recognized as one of the most critical determinants of the length of in-hospital stay, most of the early postoperative complications and ultimate outcomes [1]. Early coverage has been associated with higher union rates, and lower complication and infection rates compared to those reconstructed after 5-7 days [2–5]. Furthermore, early reconstruction improves flap survival, as microsurgical free flap integration becomes more challenging with a delay due to an increased prothrombotic environment, tissue edema and the increasingly friable vessels. Only those patients presenting to facilities with an actual dedicated ortho-plastic trauma service are likely to receive definitive treatment of a severe open tibia fracture with tissue loss within the established parameters of good practice [6]. "Fix and flap" has sometimes been recommended for specialist hospitals where the expertise is available. Antibiotic bead pouches to decrease infection rates have long been advocated when there is segmental tissue loss, gross contamination or established infection as pre-flap tissue infection seems to be an independent predictor of adverse flap and skeletal reconstruction outcomes [7,8].

Level IV series of free tissue transfer to address open traumatic wounds with accompanying fractures have been published since the first free tissue transfer for soft tissue coverage by Buncke in 1970 [9]. In 1986, Godina advocated early soft tissue coverage on a review of 532 patients based on an increased rate of flap failure in those wounds open > 72 hours [10]. However, during that time period, infection management and particularly the care and treatment of osteomyelitis were poorly understood, and dogma existed that simply the placement of a free tissue transfer over infection in the form of infected hardware or osteomyelitis was enough to treat and cure the infection. It took a great deal of time to break this dogma. Various series advocate the need for early soft tissue coverage in these cases, due to exposed soft tissue as well as the results of higher flap failure and often accompanying late infection rate [11-13]. These studies are found to be flawed in multiple respects, which include the lack of expertise and knowledge in the diagnosis and treatment of existing infection [12], low volume with resultant lack of expertise [11,13] and the inaccurate conclusion that time of flap placement could in any way affect the probability of successful bony union.

Many good studies have appeared confirming what the experienced non-union surgeon and microsurgeon know: that flap survival depends upon a decolonized and "living wound." Harrison et al. performed a thorough literature review of articles published from 1995–2011, and performed meta-analysis of 15 articles meeting inclusion criteria. They reported no difference in outcome between when free tissue transfer was performed and survival of the flap or eventual outcome [14]. Theodorakopoulou et al. reported a systematic review of 11 studies of war-related high energy extremity injuries treated with free tissue transfer in the subacute period (9 days to 3 years post-injury). There was no direct association to time of flap placement with a 95.5% free flap success rate in this particularly complex patient population [15].

Since 2000, numerous independent case series by experienced microsurgeons have also shown no difference in outcome in regard to timing of free flap placement [16-20]. These represent well-executed tissue transfers except for one series with a higher overall but uniform flap failure rate [19]. The consistent finding was that timing of free tissue transfer was not a direct cause of failure of flap survival.

The original work of Godina seems now to be outdated and not applicable to current surgical practice as it relates to timing of free tissue transfer of traumatic wounds.

QUESTION 3: Should open fracture wounds be closed primarily or closed secondarily? If closed primarily, which ones and under what criteria?

RECOMMENDATION: Yes. Primary wound closure of many open fracture wounds appears to be a safe and likely beneficial strategy in the modern setting of improved debridement techniques, better methods of fracture stabilization, and improved utilization of early systemic antibiotic administration. It appears safe for lower grade open fractures and a subset of higher-grade open fractures when the wound is deemed appropriate for primary closure on a clinical basis.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

METHODS

Randomized controlled trials, nonrandomized trials, prospective and retrospective observational studies were eligible for inclusion. We searched Medline, Embase, CINAHL, and the Cochrane Central Register of Controlled Trials (CENTRAL) up to March 2018 for published studies without language restriction. Our search strategy, including keywords and MeSH headings, are provided in the Appendix. Eligible studies met the following criteria: (1) all patients included in the study had an open fracture, (2) infection was an outcome variable and (3) there was a comparison between patients with wounds closed primarily and secondary wound closure. Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) criteria were followed. The initial search resulted in 303 papers. After removal of duplicates and screening of titles and abstracts, 12 articles were assessed and reviewed.

RATIONALE

The traditional practice of leaving all open fracture wounds open for repeat debridement at a later point in an effort to minimize risk of deep infection has changed over time. Many surgeons now routinely close most open fracture wounds at the time of initial debridement and fixation, particularly in lower grade open fractures and when wound severity and contamination are judged to be appropriate for primary closure.

A systematic review of the literature reveals no level I randomized trials in support of the practice of primary wound closure for open fractures, and the literature supporting this approach is consistently in favor of the practice, but it is also relatively weak. There is a group of more recent studies that has uniformly demonstrated lower surgical site infection rates with primary closure than with secondary closure for various open fractures in adults and children [1–7] and only one older study showing higher infection rates with primary closure [8]. However, all of these studies are methodologically limited as they do not account for selection bias between the less severe wounds that were closed primarily and the more severe wounds that were closed secondarily. As wound severity is very strongly associated with infection rates, this bias is important enough that results from these studies provide only limited insight on this issue except to point out that primary closure of some open fractures does not seem to be associated with high infection rates.

Other authors have provided similar data outlining low rates of infection utilizing a practice of primary wound closure in the vast majority of open fracture cases [9,10]. DeLong et al. used primary closure in 88% of type I, II and IIIA open fractures and had a 4% infection rate [9]. Similarly, Moola et al. used primary closure in 86% of 297 fractures and had a 4.7% deep infection rate [10]. However, while reassuring that primary closure of the majority of open fractures appears to result in an acceptable infection rate compared to historical controls, these studies are similarly methodologically limited as they lack a control group, so it is unknown if a practice of using more secondary wound closures in these patients would have resulted in a higher or lower infection rate.

One double-blind, randomized trial was published in 1993 using a factorial design to compare primary to delayed wound closure as well as the type of antibiotics used [11]. Although the random design is appealing, the sample size of only 82 patients with a low event rate presents a substantial risk of type II error and this study is very underpowered for the outcome of surgical site infection. The cohort only had two deep surgical site infections, so its conclusion that primary closure is safe is reassuring in that there was not a high infection rate in this group, but of limited value in comparing this practice to secondary closure.

The safety of primary closure was also demonstrated in a comparison between two South African trauma centers, one that used primary wound closure and one that did not [12]. This study also concluded that primary closure was safe, but again it was underpowered with a sample size of only 95 patients and an overall infection rate of only 3.3 % (3 patients). Therefore, there is significant risk of type II error with this study, and it therefore cannot provide

sufficient evidence regarding any potential difference in outcomes between the two closure strategies.

Two recent case-controlled studies provide the best evidence in support of this practice while attempting to address the issue of selection bias while also having adequate sample size and event rates to exhibit adequate statistical power. Jenkinson et al. used a propensity-matched cohort study design to demonstrate a lower infection rate in primary wound closure (4%) vs. secondary wound closure (18%, p = 0.0001) even after only including patients matched for likelihood of receiving delayed closure using propensity matching [13]. Scharfenberger et al. collected data prospectively and matched their patients to historical controls from a previous study on factors thought to predict likelihood of surgical site infection and also demonstrated that primary closure had a lower infection risk (4% vs. 9%, p = 0.001) [14]. Although both of these studies are methodologically superior to previous efforts to compare the effect of wound closure strategy on infection rates, the authors point out that there is still risk of unmeasured selection bias and a randomized trial is needed to rigorously compare the efficacy of these two closure strategies.

QUESTION 4: What are the evidence-based recommendations for the use of negative pressure wound therapy (NPWT) in open fractures and traumatic wounds?

RECOMMENDATION: NPWT is an appropriate dressing in the short-term management (< 7 days) of complex traumatic wounds over open fractures, prior to definite soft tissue closure. NPWT is not superior to other sealed dressings and has increased initial cost.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 86%, Disagree: 9%, Abstain: 5% (Super Majority, Strong Consensus)
Note: Please see Question 2 under Section 1.2. Prevention Risk Mitigation for additional rationale regarding NPWT.

METHODS

A comprehensive literature review was performed to identify all studies on the use of NPWT for the treatment of open fractures and traumatic wounds. We searched Ovid Medline, Scopus, and the Cochrane Central Register of Controlled Trials (CENTRAL) up to May 2018 for published studies. The search strategy, including keywords and MeSH headings, are provided in the Appendix. Eligible studies

met the following criteria: (1) all patients included in the study had an open fracture or traumatic wound, (2) infection was an outcome variable and (3) NPWT was the intervention. Exclusion criteria were non-English language articles, nonhuman studies, retracted papers, case reports, review papers, studies without clinical follow-up/infection rates, and technique papers without patient data. Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) criteria were followed. The initial search resulted in 247 papers. After removal of duplicates and screening of titles and abstracts, 26 articles were assessed and reviewed.

RATIONALE

Traumatic wounds and wounds over open fractures are at increased risk of developing infection due to contamination from injury, impaired blood flow, progressive soft tissue necrosis and prolonged exposure to hospital environment [1]. To minimize this risk, wounds are treated with thorough irrigation and debridement (I&D) followed by primary closure when possible or coverage with a graft or flap. Prior to definitive coverage, traditional occlusive dressings with sterile gauze had been the standard choice. Recently, there has been an increasing trend in using NPWT or vacuum-assisted closure (VAC) for wound management prior to coverage [2]. Proponents of this new method cite the following advantages to support its use: decrease tissue edema, enhance local blood flow, limit or prevent infection, improve flap rates and possibly reduce the overall need for flaps.

We performed a systematic review of the literature, as detailed above, to determine the evidence-based role of NPWT in the treatment of traumatic wounds and open fractures.

We found a group of studies supporting the use of NPWT in the treatment of traumatic wounds and open fractures. The study populations were a mix of children and adults with either traumatic wounds or open fractures, all of whom received NPWT. They found that NPWT was safe and effective and resulted in similar or lower infection rates, reduced flap complications, reduced graft size and decreased need for free flaps compared to historic controls [3–10]. However, while promising, all the studies were retrospective case series that were methodologically limited in that they lacked a comparative group and were retrospective in nature.

Eight studies compared NPWT to traditional gauze in the management of acute traumatic wounds or open fractures. Five were prospective randomized control trials, and three were retrospective case control studies. The three retrospective studies evaluated open tibia fractures and found NPWT to have significantly lower rates of infections (8.4-10 % vs. 22.6-33%), wound complications and flap failures compared to traditional gauze [11–13]. These findings are encouraging but are susceptible to the inherent limitations of retrospective studies, most notably selection bias.

The best evidence to support NPWT was found in four prospective randomized control trials comparing NPWT to traditional gauze in patients with acute traumatic wounds or open fractures. Three studies evaluated infection rate as an outcome. Two of the 3 studies showed significantly decreased infection rate with NPWT (4.6-5.4% vs. 22-28%) compared to gauze [14,15], while the other study found no difference between the two [16]. With regards to healing time, 2 of the prospective randomized control trials studied time to granulation as an outcome and both showed NPWT to be superior to gauze dressings [16,17].

With regards to duration of NPWT treatment, 3 studies retrospectively evaluated cases of traumatic wounds or open fractures treated with < 7 days of NPWT prior to wound coverage versus > 7 days of NPWT prior to wound coverage and compared them in terms of infection rate and reoperation rate. All 3 studies found a higher infection rate in cases treated with > 7 days of NPWT and concluded that while NPWT can be helpful in the management of traumatic wounds, its use should be limited to < 7 days or risk of infection increases [18–20]. However, all of these studies are methodologically limited, as they do not account for selection bias between the less severe wounds that were covered earlier and the more severe wounds that required longer time until coverage. As wound severity is very strongly associated with infection rates, this bias is important enough that results from these studies provide only limited insight on this issue. Another retrospective case series evaluated open fractures treated with I&D and NPWT prior to flap coverage. All patients had > 3 days, mean 18 days, of NPWT as they were treated on a delayed basis following stabilization and then transfer to their referral center for coverage. They found low rates of flap loss and infection, comparable to historical controls of patients treated with less than three days before definitive coverage [21].

There is an increasing body of data supporting NPWT as an adjunctive modality at all stages of treatment for traumatic wounds and open fractures. There is an association between decreased infection rates and decreased healing time with NPWT compared with gauze dressings. There is evidence to support NPWT beyond 72 hours without increased infection rates although prolonged use greater than 7 days may actually increase the risk of infection. At this time, NPWT use for traumatic wounds and open fractures requires extensive additional study.

3.7. TREATMENT: OUTCOMES

Authors: Mustafa Citak, Carl Haasper, Kenneth Egol, William T. Obremskey, Hussein Abdelazia, Philip Linke

QUESTION 1: What is the most appropriate outcome measurement (clinical, radiographic, laboratory, etc.) for management of early infection after fracture fixation (IAFF)?

RECOMMENDATION: Fracture healing and infection control seem to be the most appropriate outcome measure to monitor the response to management of early IAFF. Secondarily, treatment success following infection management after fracture fixation is best assessed using a combination of the patient's clinical picture and laboratory examinations such as tissue cultures, erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP).

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 70%, Disagree: 10%, Abstain: 20% (Super Majority, Weak Consensus)

RATIONALE

Regardless of the fracture site, primary fixation method, depth of the infection, culture results, nature of the fracture (closed or open) or chosen treatment algorithm for management of the infection, fracture healing seems to be the most appropriate final outcome measure for the treatment of an early IAFF. It must be noted that there remains substantial heterogeneity with wide variability in the definition of an early infection with regard to the time of its onset.

IAFF is one of the most serious complications in orthopaedic trauma surgery, which can impair fracture union, lead to poor functional outcomes or even result in loss of the extremity [1,2].

The management of IAFF and that of periprosthetic joint infection (PJI) differs from each other in some aspects. When treating an early IAFF, the primary aim should be the achievement of fracture healing to avoid delayed union or nonunion rather than immediate eradication of the infection [1,3].

Complicating infection management is the fact that there is no clear consensus with respect to what constitutes treatment success. Previous studies have defined the success of infection management based upon factors such as bony healing, clinical examination, culture results and the laboratory markers ESR and CRP.

To identify the best available outcome measure for the management of early infections after fracture fixation, we included all publications that reported on outcomes following management of early IAFF [4–37]. However, we found substantial heterogeneity in the definition of an early infection with regard to the time of its onset, one that varies from two weeks to five months [4,6,10,12,16,18,22,25–28,31].

Several papers reported on the clearance of the infection or its recurrence, either exclusively or with further outcome measures; other studies on the functional and clinical outcome or on the wound and soft tissue healing and few studies on the mortality rate. There are only limited number of reports on laboratory, microbiological or histological investigations as outcome measures [33,35–37].

It is important to note, that any cause of inflammation will trigger an increase in the patient's ESR and CRP. For example, surgery-related tissue damage and practices such as reamed intramedullary nailing have been shown to trigger a systemic inflammatory response and can lead to elevated ESR and CRP in the early postoperative period [36,37]. While the sensitivity of acute phase reactants for the presence of inflammation is high, non-infectious etiologies must always be considered. Recent studies have demonstrated that tissue

histology is one option for the confirmation of infection when tissue cultures are inconclusive; however, this technique is labor intensive and also prone to false negative findings [33,35].

The most common outcome measure in most studies was fracture healing or bony union [4–32]. The vast majority of identified studies have only a low to moderate level of evidence with retrospective case series designs and relatively small sample sizes. Moreover, measuring the outcome of a specific management strategy was the main focus of only a few studies. Regardless of fracture site, primary fixation method, depth of the infection, culture results, nature of the fracture (closed or open) or chosen treatment algorithm for the infection, outcome measures were extracted and analyzed. Due to the considerable heterogeneity, some descriptive analysis was also performed [4–32].

There were five studies with a relatively large case series. Rightmire et al., Berkes et al., Al-Mayahi et al., Hellebrekers et al. and, recently, Kuehl et al. reported on the outcomes after management of an early or acute IAFF of upper and lower extremity as well as pelvis and spine within the first four months in 69 patients, six weeks in 123 patients, five months in 71 patients, three months in 44 patients and three weeks in 49 patients, respectively. Besides the cure of the infection, fracture union was an important outcome measure in three of them. In the studies by Hellebrekers et al., Berkes et al. and Rightmire et al., in which open fractures were also included, fracture union was achieved in only 63%, 71% and 68% with implant retention, respectively. Implants had to be removed due to recurrence of infection in many cases [4,16,21,25,27].

The failure rate following IAFF of the ankle was 28% among the early infected cases (within the first six weeks), which could be related to persistence of the infection, a non-union or post-traumatic arthritis [22]. In the study by Zalavras et al., infection recurred in three of four identified infections within the first three weeks after ankle fracture fixation that had been managed with debridement and retention of the implant [9]. In contradistinction, Ziegler et al. have recently reported a 100% success rate with healing of ankle fractures without remissions following debridement and retention following IAFF that definitely occurred within three months after surgery [14].

Regarding IAFF with intramedullary nailing of the femur and tibia, there was only one infected non-union case from a total of 13 acute infections within the first month in the retrospective study performed by Chen et al. There was no significant difference regarding the time to fracture healing between cases with retention of the nail and those with nail exchange [31]. Among the included patients with infected intramedullary nails in the three older studies, only a few cases with an early infection within the first three weeks could be identified and delayed union had been observed [11–13].

In another prospective multicenter cohort study reporting on IAFF of the tibia, 56% of the fractures healed radiographically at one year, compared to 88% of those that were uninfected, and the time to union was significantly longer than that for the noninfected fractures. However, only 5 from 23 infected cases were reported to be early infections [15]. Delayed union was also observed in 3 out of 15 infected tibia and femur fractures treated with non-contact plates due to IAFF within 10 weeks after primary surgery [19].

Short- and long-term mortality rate was the outcome measure following management of IAFF within three months after surgery of the hip in the retrospective studies by Duckworth et al. and Edwards et al. [24,26]. Partanen et al. also performed a similar but matched control analysis although not all included cases were early infections. Beside the functional outcome and mortality rate, fracture healing was also analyzed. Failure to union was observed in 8 out of 19 cases, as infection most likely impaired fracture healing [29].

Deep early IAFF of proximal or distal humeral fractures treated by plate osteosynthesis had a high non-union rate, resulting in a poor functional outcome [20,28].

Pin tract infections in the form of K-wire fixation or external fixators can be managed conservatively and spontaneous fracture healing can be achieved with resolution of the infection [7,17,23].

Fracture union was also the common outcome measure to assess the success of management of IAFF of flat bones including the ribs, clavicle or mandible [5,18,30,32]. It can be evaluated both clinically and radiologically [5,10,14,16,17,25].

Even in late phases, the eradication of infection with restoration of an acceptable functional outcome is definitely the ultimate goal when treating an IAFF. Regardless, at this time fracture healing seems to be the most appropriate outcome measure in the case of an early infection. As soon as fracture healing is achieved, removal of the implant for the purpose of definitive eradication of infection can be considered.

PART XI

BIOFILM

Section 1: Formation

Section 2: Disruption

Formation

Authors: Mark Smeltzer, Manjari Joshi, Mark Shirtliff, Daniel G. Meeker, Jeffrey B. Stambough, Janette M. Harro

QUESTION 1: What is the life cycle of biofilm and the mechanism of its maturation?

RESPONSE: A biofilm may be defined as a microbe-derived sessile community characterized by organisms that are attached to a substratum, interface or each other are embedded in a matrix of extracellular polymeric substance and exhibit an altered phenotype with respect to growth, gene expression and protein production. The biofilm infection life cycle generally follows the steps of attachment (interaction between bacteria and the implant), accumulation (interactions between bacterial cells), maturation (formation of a viable 3D structure) and dispersion/detachment (release from the biofilm). The life cycle of biofilm is variable depending on the organism involved. There are characteristics in the life cycle of biofilm formation. These include attachment, proliferation/accumulation/maturation and dispersal. Biofilm can either be found as adherent to a surface or as floating aggregates.

LEVEL OF EVIDENCE: Strong (this is a scientific review)

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

PRE-MEETING RATIONALE

To answer this question the authors searched Pubmed and Google Scholar between January 1950 – August 2018. Search words included: biofilms, biofilm formation, bioflm life cycle, staphylococci biofilms, Gram positive organisms, pseudomonas aeruginosa biofilms, antibiotic resistance and prosthetic joint infections (PJIs). Relevant papers based on the above search words were reviewed.

Most studies found were animal studies, laboratory studies, in vivo studies and a few clinical studies. Due to time constraints, complete systematic review of the literature could not be performed.

A biofilm may be defined as a microbe-derived sessile community characterized by cells that are attached to a substratum, interface or each other are embedded in a matrix of extracellular polymeric substance and exhibit an altered phenotype with respect to growth, gene expression and protein production [1]. Biofilm thickness can vary between a single cell layer to a thick community of cells embedded within a polymeric matrix. Recent structural analyses have demonstrated that these biofilms possess a sophisticated architecture in which microcolonies can exist in discrete pillar or mushroom-shaped structures [2]. Between these structures, an intricate channel network provides access to environmental nutrients.

PJI can be initiated through hematogenous spread or by direct seeding via an overlying infection, penetrating trauma or contamination during surgical implantation of the prosthesis. Regardless of the seeding source or microbial species, the stepwise progression of the infection is dependent upon biofilm formation and maturation.

The biofilm infection life cycle generally follows the same steps of attachment (interaction between bacteria and the implant), accumulation (interactions between bacterial cells), maturation (formation of a viable 3D structure) and dispersion/detachment (release from the biofilm). This progression is mediated by the interplay of a number of microbial, host and environmental factors, and these are usually different in varying microbial species or even strains within species. A rapid stage progression can be seen with virulent, biofilm-forming pathogens in a susceptible host (e.g., a virulent *Staphylococcus aureus* (*S. aureus*) strain in a host with immunosuppression). In contrast, an infecting microbe with slow growth and low virulence (e.g., *Cutibacterium acnes* – formerly *Propionibacterium acnes*) in a healthy host capable of suppressing biofilm formation can produce an indolent infection with delayed progression.

By adopting this sessile mode of life, biofilm-embedded microbes enjoy a number of advantages over their planktonic counterparts. One advantage is the ability of the polymeric matrix to capture and concentrate a number of environmental nutrients, such as carbon, nitrogen and phosphate [3]. Another advantage to the biofilm mode of growth is it enables resistance to a number of removal strategies, such as antimicrobial and antifouling agent removal, shear stress, host phagocytic clearance and host oxygen radical and protease defenses. This inherent resistance to antimicrobial factors is mediated in part through very low metabolic levels and drastically down-regulated rates of cell division (e.g., small colony variants) of the deeply embedded microbes [4]. While low metabolic rates may explain a great deal of the antimicrobial resistance properties of biofilms, other factors may play a role as well. One such factor may be the ability of biofilms to act as a diffusion barrier to slow down the penetration of some antimicrobial agents [5]. For example, reactive oxidative species may be deactivated in the outer layers of the biofilm, faster than they can diffuse into the lower layers [6].

The last advantage of the biofilm mode of growth is the potential for dispersion via detachment. As mentioned, micro-colonies can exist in discrete, mushroom-shaped structures. These microcolonies may detach under the direction of mechanical fluid shear or through a genetically programmed response that mediates the detachment process [7]. Under the direction of fluid flow, this microcolony travels to other regions of the host to attach and promote biofilm formation on virgin areas. Therefore, this advantage allows a persistent bacterial source population that is resistant to antimicrobial agents and host immune clearance, while at the same time enabling continuous shedding to promote bacterial spread.

S. aureus Biofilm Formation

Although many bacterial pathogens are capable of forming biofilms in a range of clinical contexts, *S. aureus* is the main etiological agent associated with PJI.

The initial phase of biofilm formation is characterized by the attachment of planktonic cells to a surface. In a planktonic mode of growth, *S. aureus* up-regulates the expression of key mediators for immunoavoidance (e.g., Protein A) and the attachment to biotic surfaces. These mediators are a variety of proteins anchored in the

cell wall, the largest group of which are termed microbial surface components recognizing adhesive matrix molecules (MSCRAMMs) [8]. Binding of MSCRAMMs to host components such as fibronectin, fibrinogen, collagen and cytokeratin are an important first step in the attachment of *S. aureus* to initiate biofilm formation [9]. Attachment to abiotic surfaces is also determined by properties and physicochemical characteristics of the abiotic surface as well as the bacterial surface, with hydrophobic and electrostatic interactions playing a major role [10].

However, it is worth noting that many abiotic surfaces, as is the case with many implanted medical devices, are rapidly coated in host matrix components upon implantation. Therefore, surfaces that have been engineered to be "biofilm-resistant" have failed in vivo since *S. aureus* mediates attachment to these conditioned surfaces [11]. The presence of a devitalized surface coated with host extracellular matrix proteins decreases the infectious dose required to cause infection to less than 100 viable *S. aureus* cells, thereby increasing the ability of *S. aureus* to cause biofilm infections by over 75,000 fold [12].

Following this initial attachment, bacteria proliferate and produce an extracellular matrix (ECM), often referred to as slime or glycocalyx, comprised of proteins (both host derived and bacterial), carbohydrates and extracellular DNA (eDNA). These serve as a scaffold for maturation and 3D structuring of the biofilm [11]. Ultimately, through coordinated degradation of ECM via proteases, nucleases, delta hemolysin and other factors (e.g., phenol soluble modulins), bacterial cells are released from the biofilm with the potential to seed secondary sites of infection [13]. Below is a brief discussion of the factors and mechanisms responsible for these stages of the *S. aureus* biofilm life cycle.

The next phase of biofilm formation entails the proliferation and accumulation of attached bacterial cells. During this early phase, intercellular attachment plays a key role in stabilizing the early biofilm before a significant amount of ECM can be produced to protect the attached cells from disruptive forces such as shear force [11]. One key contributor to intercellular adhesion is the polysaccharide intercellular adhesin (PIA), first studied in *Staphylococcus epidermidis* [14]. The MSCRAMMs (discussed above) and certain cytoplasmic proteins shown to bind to eDNA are also know to contribute [15–17]. Together, these factors not only play a role in early intercellular adhesion but also constitute major components of the ECM produced by biofilm-associated cells.

Recent studies utilizing technology allowing for nearly real-time evaluation of biofilm progression have suggested the addition of a stage of biofilm development following proliferation/accumulation referred to as an "exodus" phase [18]. This exodus phase is characterized by an early dispersal event with a reduction in total biomass from a biofilm. This is reportedly achieved through the coordinated bacterial expression of secreted nucleases by a subpopulation of bacterial cells resulting in degradation of eDNA and subsequent bacterial release [18]. The purpose of this phase and its necessity for the overall progression of the biofilm life cycle remain to be determined. However, given the timing of these observations within the overall progression of biofilm formation, it has been suggested that a dynamic shift occurs in which early events are largely protein-mediated and subsequent events are mediated by both protein and eDNA [11]. Although some literature would suggest that certain biofilms tend to be exclusively dependent upon PIA, protein or eDNA, these studies propose a more dynamic model of development with temporal and spatial changes in ECM components [11].

The maturation phase of the biofilm life cycle entails the 3D structuring of biofilms into classic architectural structures (towers and mushroom-like structures) and the development of microcolonies displaying some degree of phenotypic diversity [10,11]. This complex structuring is coordinated through the balance of adhesive and disruptive factors [10]. Adhesive factors include the ECM components discussed above such as PIA, proteins and eDNA. Disruptive factors include enzymes that degrade these components such as proteases and nucleases, as well as the surfactant-like molecules, phenol-soluble modulins (PSMs). These disruptive factors allow for the remodeling and maturation of biofilm structures. For example, studies have demonstrated that channels are created throughout a biofilm via the surfactant-like activity of PSMs, allowing nutrients to reach deeper layers of the biofilm [19]. Therefore, these studies describe biofilm maturation as a subtractive process. Alternatively, some studies suggest an additive process of maturation from observations of microcolonies emerging from slower growing basal layers of biofilms [20]. It is likely that both additive and subtractive processes contribute to the complex structuring observed during biofilm maturation.

The final step of the biofilm life cycle involves the dispersal of cells with the ability to travel to distal sites to disseminate infection. The mechanism by which *S. aureus* regulates this step is largely mediated by the accessory gene regulator (*agr*) quorum-sensing system [19,21]. The *agr* system responds to cell density through the accumulation of signal molecules, allowing for dispersal to occur once a threshold density is reached [22]. The *agr*-regulated factors that have been proposed to mediate dispersal include secreted proteases and resultant degradation of protein components of ECM [23]. Dispersal has also been proposed to be mediated by the *agr*-mediated production of PSMs, which act by disrupting molecular interactions within biofilms [19].

In addition to these staphylococcal factors responsible for PJI development, the complicit nature of the host towards biofilm formation also plays a role. In an early *S. aureus* biofilm infection, the intense inflammatory response is produced by the host. *S. aureus* is readily able to resist clearance from the host through a large number of virulence factors that specifically attack the host and promote immunoavoidance. The expression of *S. aureus* virulence factors, timed by the quorum sensing system, promotes the host to release T_H1 cytokines, including interleukin (IL)-12, interfenn gamma (IFN-γ), tumor necrosis factor alpha (TNF-α), and IL-17 resulting in a shift of the adaptive immune system to an ineffective T_H17 and T_H1 cell-mediated immune response. This type of response is incapable of clearing a biofilm infection, thereby enabling *S. aureus* to form a fully mature biofilm and a persistent infection. The other branch of adaptive immunity, the T_H2 antibody-mediated response, is readily effective at clearing the infection in the early phase of biofilm formation before it progresses to a fully mature phenotype. However, this antibody-mediated response is shut down both by the host cytokines associated with the initial response to *S. aureus*, most notably IFN-γ, and by the *S. aureus* production of superantigens, capsule and other toxins. Additionally, *S. aureus* produces a number of highly immunogenic decoy antigens (e.g., lipase) that augments the ability of *S. aureus* to cause disease and reduces antibody production against more vital antigens [24]. By the time the antibody-mediated immune system recovers and mounts an effective response against the biofilm infection, the fully mature biofilm is able to resist clearance. Even if cleared through surgical intervention and infection resolution, this host immune response manipulation and variable antigen expression allows *S. aureus* to re-infect patients throughout their lifetime.

Once in this fully mature phase, the infection can remain quiescent for years or even decades, or more typically, will show remarkable signs of chronic inflammation [25]. This host response is often due to the metastasis of metabolically active and virulent planktonic subpopulations that have dispersed/detached from the localized biofilm aggregate. Antibiotic therapy is effective against these

active populations allowing for temporary suppression of clinical signs and symptoms of the underlying biofilm disease. However, upon antibiotic treatment cessation, exacerbation of the disease will necessarily result.

Biofilms Formed by Other Microbial Species

In addition to *S. aureus*, a number of other microbial species are able to form infectious biofilms in PJIs [26]. These include other facultative anaerobic, gram-positive, non-motile bacterial species, including coagulase negative staphylococci and *Streptococcus* and *Enterococcus* species. The stages of biofilm formation are similar, and these microbes use a number of homologs to the biofilm-associated virulence factors already described for *S. aureus*. Species other than these gram-positive microbes contribute towards PJI, particularly the facultative anaerobic gram-negative bacilli, including *Escherichia coli* and *Pseudomonas aeruginosa* and anaerobes to a lesser extent.

Gram-negative bacterial biofilms, especially *P. aeruginosa,* have long been studied in the biofilm research field due to their ubiquitous nature in the environment and disease, and their preponderance in chronic wounds and cystic fibrosis lung infections. Although the stages progress through early attachment, mature attachment, accumulation, maturation and dispersion/detachment, the mechanisms by which these steps are accomplished show important differences to gram-positive pathogens.

The motility provided through flagella allows *P. aeruginosa* to facilitate close association with surfaces, such as those in indwelling medical devices. The microbial cells will then proceed to irreversible attachment. Additionally, Type IV pili provide for differential virulence factor production associated with shear stress as well as allow subpopulations to migrate on the surface through twitching motility. As the biofilm accumulates, the formation of complex multicellular structures occurs that demonstrate heterogeneity of nutrients, pH and oxygenation. During maturation, the development of membrane blebs, nanofilaments, eDNA structural support and electrical coupling of the embedded bacterial cells also occurs. As the population swells, the homoserine lactone quorum sensing system induces the production of the surfactant and anti-leukocyte pseudomonal rhamnolipids to prevent clearance and add to the burgeoning inflammatory response. The microbes can then either disperse as single-celled planktonic populations or detach from the biofilm in large conglomerated flocs that allow for metastasis of the infection while enjoying the protective environment of the biofilm matrix.

Clinical Relevance: Treatment and Resolution

During the early acute stage of infection and inflammation, the biofilm is in an early accumulation phase. During this phase, the growing biofilm demonstrates higher susceptibility to antimicrobial therapy than the fully mature, quiescent and metabolically inactive biofilm phenotype. This increased susceptibility to antimicrobial therapy during the acute phase of PJIs translated into efficacious treatment without surgical intervention [28]. When effective combination antimicrobial therapy was used alone to treat PJIs with clinical signs of less than one month in duration, over 83% of patients were successfully treated without surgical intervention. However, once symptoms lasted for greater than six months, successful treatment of antibiotic therapy fell to just over 30%. Therefore, the potential for effective therapy of PJIs without surgical intervention may be a possibility if the infection is diagnosed early and targeted antibiotic therapy is quickly initiated with emphasis on adding Rifampin/Rifampicin when a *Staphylococcus* spp is the etiological agent. After this early therapeutic window, proper surgical debridement along with combination antibiotic therapy is necessary for optimal infection resolution.

Clinical Relevance: Diagnosis

Rapid, effective and sensitive discovery and identification and antibiotic sensitivity determination of the pathogenic bacterial species must be accomplished in order to effectively combat PJIs. Once identified, effective therapeutic counter-measures and treatment can be applied. Currently, pathogen identification requires microbial culture followed by diagnostic analyses that normally require additional rounds of replication in culture or purification of specific bacterial/fungal products. At best, microbial identification may require days to weeks, depending on the growth rate of a specific pathogen. These limitations of bacteria are dramatically exacerbated in diagnosing and speciation of the etiological agent in PJIs. Culture from tissue samples can be effective during the early stages of infection when the biofilm is in an accumulation phase and planktonic populations are present. However, all too often, patients have received antimicrobial therapy prior to proper tissue sampling, thereby eliminating the easily detected planktonic populations, leaving behind only small microbial aggregates that are often missed during biopsy. Also, as the biofilm matures, the host immune response walls off the infectious nidus to form these same hard-to-detect biofilm aggregates.

In conclusion, understanding the progression of biofilm life cycles and the mechanisms that pathogens use to regulate this progression is essential for the development of therapeutic approaches aimed at preventing, disrupting and eradicating biofilm-associated infections.

QUESTION 2: What surface properties favor biofilm formation?

RESPONSE: The attachment of bacteria to implant and biological surfaces is a complex process, starting with the initial conditioning film. Roughness, hydrophobicity/hydrophilicity, porosity, pore topology and other surface conditions are the key factors for microbial adhesion. Because of the huge variety of these factors, most of the studies directed at bacterial attachment to the implant surface were limited to specific surface conditions since it is difficult to examine the plethora of parameters concomitantly. There are variable conclusions among the available basic science and animal studies relevant to this topic, many of which will be described in greater detail below. Bacteria can form biofilm on almost all prosthetic surfaces and biological surfaces. To date, this consensus group knows of no surface that is inimicable to the growth of biofilm in vivo.

LEVEL OF EVIDENCE: Strong

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

PRE-MEETING RATIONALE

Bacterial biofilms are widely known to contribute to the etiology of chronic infections and implant-associated infections. Biofilm development commences upon formation of a conditioning layer conducive to bacterial attachment, the attachment itself and secretion of a slime-like substance [1]. It is this secretion that enables biofilm formation and ultimately introduces antibiotic resistance and resistance to the host immune system. Several surface properties have been identified that can influence biofilm formation, these include: surface chemistry and functional groups, surface free energy and level of hydrophilicity/hydrophobicity, surface charge, micro- and nano-topography and porosity. Surface chemical composition, micro-roughness and surface free energy would appear to prevail for importance [2].

There is strong evidence that the initial attachment of bacterial species to the surface of a biomaterial is influenced by the presence of adsorbed proteins [1,3]. Wagner et al. [1] found that titanium surfaces preconditioned through exposure to blood plasma enhanced bacterial adhesion for both *Pseudomonas aeruginosa* and *Staphylococcus aureus (S. aureus)*. Likewise, a study performed by Frade et al. presented similar findings with respect to surface adhesion of *Candida albicans* (*C. albicans*) and subsequent biofilm formation on multiple surfaces after serum coating, including polycarbonate, polystyrene, stainless steel, Teflon, polyvinyl chloride and hydroxyapatite [3].

Similarly, there is also strong evidence supporting the conclusion that bacterial adherence and biofilm formation increase with the roughness of the implant surface [4,5]. A study conducted by Karygianni et al. found that *Enterococcus faecalis, S. aureus,* and *C. albicans* adhered more to a rougher implant surface relative to a smoother surface [5]. Furthermore, Braem et al. demonstrated that a porous surface coating was more susceptible to biofilm formation than a smoother titanium-based surface after exposure to *S. aureus* and Staphylococcus epidermidis *Staphylococcus epidermidis* (*S. epidermidis)* [4].

A small number of studies have also examined the impact of the hydrophobicity/ hydrophilicity of implant materials on subsequent biofilm formation [2,3,6]. For example, a study performed by Koseki et al. using *S. epidermidis* showed decreased biofilm formation on cobalt-chromium-molybdenum alloy (Co-Cr-Mo) which was attributed to its increased hydrophobicity [2]. However, two other studies showed contrary results. For instance, *C. albicans* was shown to have less metabolic activity on polycarbonate and stainless steel (hydrophilic surfaces) relative to Teflon (hydrophobic surfaces) [3]. Similarly, some studies contend that hydrophilicity has only trace impact on biofilm formation, as shown by the fact that *S. epidermidis* biofilm formation was not significantly altered by differences in surface wettability [6]. With that, findings remain inconclusive as a whole concerning the impact of implant surface hydrophilicity/hydrophobicity on biofilm formation.

Finally, there are various surface properties that are given moderate recommendations here due to their high-quality evidence but low replication in the studies presented. The first is that surface

nanostructures, such as projections and recesses, reduce overall bacterial adhesion and biofilm formation compared to smooth surfaces [7]. The second is that low nanostructure stiffness inhibits biofilm accumulation, likely due to the susceptibility of these nanostructures to shear forces [8]. The third is that calcium-incorporated oxide coatings on a titanium surface reduces bacterial colonization when compared to non-calcium modified titanium. This is due to calcium drastically decreasing the contact angle [4].

Although there is little consensus in terms of which surface properties are most definitive in contributing to biofilm formation, there are certainly strides in examining the general impact of different properties when considered individually. Due to the complexity of biomaterial properties inherent to orthopaedic implant structure—and the lack of agreement among the literature concluding the impact of these properties—we conclude that biofilm formation is favored by combinations of surface parameters, and so should be assessed as such in the development of biofilm resistant implants. Furthermore, there are few studies examining the impact of surface properties in biofilm formation among human subjects postoperatively and further clinical studies are necessitated.

QUESTION 3: Is the biofilm on orthopaedic implant surfaces permeable to neutrophils and macrophages in vivo? Are these innate immune cells (meaning any macrophages or neutrophils) capable of engulfing and killing bacteria?

RESPONSE: A mature bacterial biofilm has limited permeability to neutrophils and macrophages. Those that get through are clinically ineffective at eradicating biofilm bacteria. While neutrophils and macrophages are capable of engulfing and killing planktonic bacteria, they are not innately capable of effectively engulfing and killing sessile bacteria in biofilm.

LEVEL OF EVIDENCE: Strong

PRE-MEETING RATIONALE

The most important pathogenic mechanism involved in implant-related infections is the ability of the microorganisms to form a biofilm [1], which leads to protection against environmental stress, host immune defense and antimicrobials [2]. The first cells arriving at the infection site are the neutrophils and macrophages [3]. The permeability and the phagocytosis ability of these immune cells have mainly been evaluated in two types of infection: cystic fibrosis [4–8] and device related infection, mainly catheter-related infection [9–17] and periprosthetic infection [18].

Neutrophils are innate immune cells capable of secreting an arsenal of toxic oxygen species, degrading enzymes, defensins and lipid inflammatory mediators to fight off infection [6]. These cells have shown the ability of sticking but not penetrating into a mature biofilm and phagocytizing biofilm encased microorganisms [4–8,10,11,14,19–23]. The exopolymeric substances of the biofilm matrix seem to be involved in the formation of neutrophil extracellular traps in biofilm of *Streptococcus suis* [21], *Candida albicans* [10] and *Candida glabrata* [11]. Data shows that neutrophils can destroy a two to six day old *Staphylococcus aureus* (*S. aureus*) biofilm, but a mature biofilm is capable of resisting penetration by these cells [24].

Guenther et al. studied the different behavior of polymorphonuclear neutrophils (PMNs) towards the biofilm formed by either *S. aureus* or *Staphylococcus epidermidis* (*S. epidermidis*). In the case of biofilm formed by *S. aureus*, the PMNs were observed to move across and scavenge bacteria along their path. Conversely, PMNs in contact with *S. epidermidis* biofilm were nearly immobile and phagocytized only bacteria in close proximity. Why biofilms of *S. aureus* appear more sensitive to a PMN attack compared to those produced by *S. epidermidis* is not well understood [19]. Insights on the behavior of biofilm formed by *S. epidermidis* have been offered by the in vitro and in vivo studies of Kristian et al. These authors found that *S. epidermidis* biofilms triggered higher levels of complement activation in terms of C3a formation than planktonic wild-type bacteria and isogenic ica-negative bacteria. On the other hand, a decreased deposition of immunoglobulin G (IgG) and C3b was observed in biofilm-embedded bacteria. This could possibly explain the evasion of PMNs killing [25].

Alhede et al. evaluated the role of immune system against biofilm formed by *Pseudomonas aeruginosa*. They demonstrated that both in vitro and in vivo biofilms of *Pseudomonas aeruginosa* produce

a shield of excreted rhamnolipids, which offers protection from the bactericidal activity of PMNs [26].

Arciola et al. did an extensive study of biofilm formed by Staphylococcus on an implant surface. Based on their work, PMNs were found to surround biofilm and become activated, but PMNs were not able to migrate into the biofilm, probably because of a lack of a chemotactic signal as well as by hindrance of migration into the "slimy" material. Thus, the inability of PMNs to penetrate biofilm results in progression of implant related infections. The activation of PMNs and their attempt to kill bacteria results in secretion of numerous cytotoxic and proteolytic enzymes that cannot act against bacteria but results in damaging and destroying the surrounding host tissues [27].

Macrophages become the prevailing cells and remain at the infection site a high concentration for several weeks and they are related to recognition, phagocytosis, secretion of enzymes, cytokines, chemokines and growth factors, to destroy and digest the phagocytized pathogens [3]. These cells can penetrate into a mature biofilm in a similar way as neutrophils, and phagocytize biofilm encased microorganisms, but not destroying them [9,12,13,18]. Moreover, these sessile phagocytized bacteria can even persist into peri-implant tissue inside macrophagic cells not only in experimental models, but also in the tissues of patients with intravenous catheters colonized by different bacteria [16,17]. *S. aureus* prosthetic infection in vivo model showed that limited bacterial macrophage uptake is due to inflammatory attenuation by *S. aureus* biofilm [13], which favor the transformation from M1 macrophages presents a high antimicrobial activity to M2 type inherently possesses less antimicrobial activity [13], and the cell death induction though leukocidin A/B [28] and human leukocyte antigen production [18]. At the site of staphylococcus biofilm infection, macrophages exhibit: down-regulation of interleukin (IL)-1β, tumor necrosis factor, CXCL2 and CCL2 expression, reduced bacterial uptake, minimal iNOS expression and consequent low efficiency in killing phagocytized bacteria and reduced induction of lymphocyte production of interferon-γ. These scavenging cells appear able to migrate into the biofilm but cannot clear the site from the pathogen causing the infection as their bactericidal activity appears compromised [27].

QUESTION 4: Does the timescale of biofilm formation differ between bacterial species? If so, what is the timescale for common causative organisms?

RESPONSE: Currently, there is no clinical research available to answer whether the timescale in the development of biofilm formation differs between bacterial species. In vitro studies show high variability in biofilm formation based on bacterial strains and conditions. Animal studies have demonstrated rapid (minutes to hours) biofilm formation. The group notes that the timeline of biofilm formation may not correlate with the onset of infection symptoms.

LEVEL OF EVIDENCE: Strong

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

PRE-MEETING RATIONALE

Biofilms are comprised of single or multiple species of microbial aggregates embedded in a self-produced matrix of extracellular polymeric substances. Regardless of the bacterial species, biofilm formation proceeds in known and well-defined steps. The first step or stage, adhesion, begins when bacteria sense and attach to surface of a material. The second stage is accumulation, where bacteria aggregate to form a mature biofilm. The last stage is dispersion or detachment [1]. The duration of each of these steps in biofilm formation varies from nanoseconds to hours to weeks, depending on various factors such as size of inoculum, mechanism of colonization (direct perioperative inoculation, later direct colonization due to break of barrier, bacteremic spread), surface properties of the foreign material, bacterial strain and virulence, bacterial species, host immunity, prior antibiotic usage and environmental factors, etc. [2–10].

For example, *Pseudomonas aeruginosa* (*P. aeruginosa*) contains several genes that are turned on within 15 minutes of its attachment to a surface that can be a starting point of biofilm formation [3]. Kanno et al. developed full thickness wounds on the backs of rats and inoculated them with *P. aeruginosa* carrying the green fluorescent protein gene; they found that biofilms could develop within eight hours [4]. When *Staphylococcus aureus* (*S. aureus*) was inoculated onto animal wounds, researchers found the development of clusters of cells (characteristic of a biofilm) after 6-24 hours post inoculation [11,12]. Oliveria et al. evaluated the time course evolution of biofilm in mastitis isolates and found no significant difference between *S. aureus* and *Staphylococcus epidermidis*. In their study biofilm forming ability increased with incubation period for both species [5]. Hoffman et al. researched adhesion patterns of single bacterium *Caulobacter crescentus* on a glass surface in a microfluidic device. They showed the importance of pili for hastening bacterial adhesion. In their study, irreversible adhesion events were more frequent in wild-type cells (3.3 events/min) compared to pilus-minus mutant cells (0.2 events/min) [13].

Koseki et al. [6] evaluated the difference in early biofilm formation of polysaccharide intercellular adhesin (PIA)-positive *Staphylococcus epidermidis* on five types of biomaterials and found no significant difference in biofilm coverage rate at two to four hour incubation, but at six hours post incubation cobalt-chromium-molybdenum alloy (Co-Cr-Mo) had a significantly lower biofilm coverage rate than other materials like titanium alloy (Ti-6Al-4V), commercially pure titanium and stainless steel. In this study authors point out a similar degree of smoothness across materials as a reason for no significant difference between them initially (two to four hours). In this study average roughness (Ra) was less than 10 nm [6]. This is corroborated by the previous reports that bacterial adhesion is influenced by the threshold of surface roughness at values more than 200 nm [14,15].

Some evidence suggests that bioactive substances such as hydroxyapatite may be more prone to bacterial adhesion than bioinert metals, such as titanium alloys and stainless steel [7]. Further studies have demonstrated that polymethyl methacrylate (PMMA) is capable of hosting biofilms that can cause acute, chronic and delayed-onset infections [8,9].

Biofilm adherence to biological or synthetic materials and foreign cells and resistance to antimicrobials are poorly understood. As biofilm formation can proceed through different pathways and time ranges, its detection may differ according to the time of observation. Investigational models to determine how environmental factors, such as surface geometry, physical and chemical characteristics, and local blood flow and immune system affect biofilm development on prosthetic joints are essential to further understand various bacterial biofilms and provide insight to therapeutic strategies.

QUESTION 5: Do bacteria form biofilm on the surface of cement spacer in a similar fashion to a metallic implant?

RESPONSE: Yes. While the vast majority of studies have been in vitro, there is clinical evidence that majority of bacteria are able to form biofilm on the surface of cement spacer.

LEVEL OF EVIDENCE: Strong

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

PRE-MEETING RATIONALE

The majority of data assessing biofilm growth on polymeric materials and smooth surfaces has been collected from in vitro experiments [1]. As a general outline, microbial adherence to materials occurs in the following order: latex > silicone > PVC > Teflon > polyurethane > stainless steel > titanium [1,2]. This hierarchy of materials to bacterial adherence suggests that biofilms may develop more readily on polymer-based versus metallic material surfaces. Roughness may play a role in this [3]. However, time is also an important factor to consider. Verran et al. showed that *Candida albicans* adhered to a greater degree on roughened surfaces compared to smooth [4]. In their experiment, polymeric samples were incubated for one hour, and then assessed for adhesion profiles. Similar work was performed by Taylor et al. on cobalt-chrome materials with the same conclusion [5]. Although a one-hour incubation period may be beneficial to determine initial adherence profiles, it would be difficult to compare test criteria such as these to clinical scenarios where implanted materials are present for days, weeks, months or years. Wolcott et al. have shown that time may play an important role in biofilm maturation and antibiotic tolerance [6]. Biofilms are well-known to condition surfaces and make them conducive to their growth requirements [3]. Perhaps one of the most well-known examples of this is *Streptococcus mutans*, which conditions the enamel surface that allows adherence for hundreds of other bacterial species [7]. Given enough time, biofilms may flourish on surfaces in many environments and on surfaces that may otherwise be considered less culturable [3,8,9]. In-house experiments that are in process of publication have shown that even amongst the same species, varying strains can differ in rates of biofilm formation on titanium surfaces, but over time degree of biofilm formation is similar in bench-top conditions.

The principles and problem of biofilm formation apply to bone cement and metallic surfaces used in orthopaedic applications. Biofilms have been shown to develop on both material types and adversely affect clinical outcomes [10–13]. A seminal paper published by Gristina et al. provided one of the first indications of biofilm growth on an implanted metallic implant that was found to contribute to biofilm-related infection [14]. More recently, Stoodley et al. directly observed biofilms on antibiotic-loaded bone cement associated with an infected total elbow arthroplasty [12]. McConoughey et al. have also identified bacterial biofilms on implanted components [15]. Shaw et al. observed biofilm, via methylene blue staining, that had developed on a tibial tray and other total joint components during revision surgery [16]. In multiple cases, biofilm has been observed directly on clinical samples. Due to the heterogeneous and at times difficult nature of collecting clinical samples, more highly controlled, albeit confirmatory outcomes of biofilm growth on metallic and cement materials have been obtained from in vitro and in vivo experiments.

Minelli et al. showed the ability of multiple staphylococcal bacterial strains to form biofilm on bone cement samples in all cases [17]. Neut et al. observed that slime-producing *Pseudomonas aeruginosa* can readily form biofilm on cement material, and in the biofilm phenotype it may be more tolerant to antibiotics loaded in cement than planktonic bacteria [18]. Ensing et al. assessed biofilm growth on cement material and the potential of ultrasound to remove its presence [19]. More recently in a study by Ma et al., polymethylmacrylate spacers that were removed at the time of reimplantation following treatment of infected total knee arthroplasty were shown to have high levels of bacterial DNA despite extended exposure to antibiotics [20]. Biofilm formation on metal surfaces is also well-documented [21–24]. Nishitani et al. have also observed growth of biofilms on metallic implants in mice [25]. Williams et al. have shown that over multiple days of growth in a CDC Biofilm Reactor, polymicrobial biofilms of methicillin-resistant *Staphylococcus aureus* and *Bacillus subtilis* grow similarly on smooth or rough titanium surfaces [26].

In summary, indications that biofilm forms on bone cement and metallic surfaces in a similar fashion are present from clinical samples as well as in vitro and in vivo animal studies. There are indications that bacterial cells may adhere to and form biofilms more quickly on rough/porous materials, but over time bacteria may condition material surfaces that are smoother in nature such as metal and allow biofilm to form to a similar degree.

QUESTION 6: Does *Mycobacterium tuberculosis* (*M. tuberculosis*) form a biofilm on implants?

RESPONSE/RECOMMENDATION: Few data from experimental in vitro and in vivo studies and a limited number of case reports indicate that *M. tuberculosis* has a slow, albeit significant, ability to form biofilm on metal surfaces. The group suggests that management of *M. tuberculosis* implant-related infections should be treated using the same principles as that of other implant-related infections.

LEVEL OF EVIDENCE: Strong

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

PRE-MEETING RATIONALE

Methods

A search of the English language literature on the question published during the period 1966–May 20, 2018 was conducted. The search strategy in PubMed used the terms *M. tuberculosis* and biofilm and identified 177 articles. All articles were reviewed for the response to the question. The vast majority of articles were categorized as basic sciences articles focusing on the components for tubercular biofilm formation in vitro. A systematic review to answer the provided question is not meaningful. Hence, the response of the question is answered as a summary of a narrative review.

Narrative Literature Review and Discussion

It is important to differentiate between *M. tuberculosis* and non-tuberculous mycobacterium. This review focusses only *M. tuberculosis*.

M. Tuberculosis Forms Biofilms

In the laboratory, *M. tuberculosis* shows peculiar aggregated growth, or in other words, can form organized pellicle-like structures [1]. The hallmark of biofilms is the self-production of the extracellular polymeric substance that holds the mycobacterial community together and confers phenotypic heterogeneity to

the genotypically identical cells [2]. Several studies have highlighted extracellular components within *M. tuberculosis* aggregation, including mycolic acids [3], complex sugars [4], cellulose, proteins, lipids and DNA [5,6]. In addition, *M. tuberculosis* residing within organized pellicle-like structures exhibits drug tolerance to antitubercular agents [3]. Thus, criteria of a structure to what is interpreted as biofilms are given.

M. Tuberculosis Biofilms in Humans

The clinical role of *M. tuberculosis* biofilms in humans is not fully understood. Basaraba and Ojha [7] provide convincing arguments that extracellular *M. tuberculosis* in necrotizing lesions likely grows as biofilms. Hence, mycobacterial biofilms may participate in the process of caseous necrosis and cavitation formation in lung tissue [5–7].

M. Tuberculosis Biofilms on Metal Surface

The vast majority of studies investigating *M. tuberculosis* biofilms uses polystyrene plates [8]. Ha et al. [9] compared the adherence and the biofilm formation of *Staphylococcus epidermidis* (*S. epidermidis*) with those of *M. tuberculosis* on four types of metal segments. In contrast to *S. epidermidis*, *M. tuberculosis* rarely adhered to metal surfaces and showed discrete biofilm formation. Similar results were reported by Chen et al. [10] who compared *S. aureus* and *M. tuberculosis* in vitro and in vivo. Adetunji et al. [11] analyzed *M. tuberculosis* biofilm formations on cement, ceramic or stainless steel coupons. The experimental settings in this study are difficult to transfer in an in-vivo implant model (e.g., more biofilms were formed when media containing 5% liver extract was used). However, more biofilms were formed on cement than on ceramic and stainless steel coupons [11]. Taken together, the few available data from in-vitro and in-vivo studies indicate that biofilm formation of *M. tuberculosis* on metal segments is poor in comparison to Staphylococcus spp.

Among the 66 cases reported by Veloci et al. [12], 13 (19.6%) were treated with antitubercular agents only. Hence, in these cases no surgical intervention was performed to reduce the mycobacterial load or to remove mechanically the biofilm adhering to the implant. One patient died because of far-advanced tuberculous meningitis, miliary tuberculosis of the lungs, femoral osteomyelitis and extended cold abscesses along the femoral shaft [13]. In the other cases, no failure was reported. Though only in 6 (50%) of 12 cases, follow-up results of ≥18 months after the end of therapy was available. Treatment duration ranged from 6 to 18 months. These data indicate that tubercular biofilm eradication is possible with chemotherapy only. Whether this is due to poor biofilm formation on metal implants or due to effective anti-biofilm activity of antitubercular agents cannot be assessed.

QUESTION 7: What is the role of the microbial synergy in polymicrobial infections?

RESPONSE: In polymicrobial infections, a complex environment may be formed in which microbiological interactions exist between microorganisms. Scientific evidence exists to show that combinations of bacterial species may exist whereby these can protect each other from antibiotic action via the exchange of virulence and antibiotic resistance genes, and this may be evident in adverse outcomes for polymicrobial orthopaedic implant-related infections. It is also probable that polymicrobial infections may be more likely in patients with poor immunity and tissue healing.

LEVEL OF EVIDENCE: Strong

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

PRE-MEETING RATIONALE

Varying incidences for polymicrobial infections have been reported with rates ranging from 6% to 37% [1–5]. The literature consistently demonstrates that patients with a polymicrobial infection demonstrate inferior treatment outcomes. Tan et al. reported that patients with polymicrobial periprosthetic joint infection (PJI) had a higher failure rate (50.5%) compared with monomicrobial PJI (31.5%) and a higher rate of amputation (odds ratio [OR] 3.80), arthrodesis (OR 11.06), and mortality (OR 7.88) [2]. Similarly, Wimmer et al. demon-

strated that the infection free rate after two years was 67.6% for polymicrobial infections vs. 87.5% for monomicrobial infections in a series of 77 polymicrobial PJIs [6]. In addition, Marculescu et al. demonstrated that the 2-year cumulative probability of success of polymicrobial PJIs was 63.8% compared to 72.8% for monomicrobial PJIs [7].

There are several explanations for the increased rate of failure in patients with polymicrobial PJI. Some explanations of polymicrobial infection include the following: the association with a sinus tract or a soft tissue defect; the frequent presence with difficult to treat organisms, such as Enterococcus spp and gram negatives [2,7,8]; increased comorbidities [2,7]; and microbial synergy.

Microbial synergy is defined as an interaction of two or more microbes in an infection site that results in enhanced disease by creating a more favorable condition for one another, compared to infections containing a single organism [9,10]. According to this definition, it can be appreciated that polymicrobial infection have less optimal outcome over that of monomicrobial infections because of the enhanced pathogen persistence in the infection site, increased disease severity and antimicrobial resistance [10,11]. While microbial synergy results in an enhancement of the disease, real experimental data supporting this phenomenon is still limited [12–14], which may be attributed to the complex and dynamic web of interactions that occur in natural systems [15].

Identified types of polymicrobial infections are due to: (1) changes in relative composition of individual species of microbiota [16]; (2) colonization of a pathogenic microbe of an infection site that already contains commensal microbes; and (3) colonization of a pathogenic microbe on a body they don't usually habit [17].

Several mechanisms of microbial synergy have been proposed in order to explain microorganisms interactions during polymicrobial infections: (1) metabolite cross-feeding: reported as the consumption of metabolic end-products by one of the microbial communities involved and optimization of local environment with the metabolic end-products [9,18,19]; (2) dedicated signaling systems: capacity of many microorganisms to communicate and coordinate activities as a group through low molecular weight signals, called "quorum sensing" [20]; (3) stimulation of resistance to the immune system: production of chemical substances that induce resistance to immune system like outer membrane proteins that inhibits immune pathways [9,18]; (4) suppression of the immune system by commensal bacteria: promotion of growth environment for commensal pathogens [9,21,22]; (5) direct contact: formation of biofilm by membrane-bound structures (adhesins) between microbes [23,24]; and (6) increased virulence of the organisms: production of substances that enhance the virulence of other bacteria [9].

QUESTION 8: Is the mapping of biofilm to a particular component or anatomical location an important consideration in management of implant related infections?

RESPONSE: At present, mapping of biofilms is only possible in the laboratory, not in the clinical setting. Therefore, it is of unknown clinical importance in relation to management of implant-related infections.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

PRE-MEETING RATIONALE

Total joint replacement has become a vital tool for the treatment of end-stage osteoarthritis of the knee and hip and has the potential to substantially improve a patient's quality of life when successful. However, periprosthetic joint infection (PJI) is a dreaded complication of arthroplasty procedures that often results in expensive intravenous antibiotics, longer hospital stays and numerous negative effects related to patient morbidity [1]. Occurring at a rate of around 0.5-2% across all primary total joint procedures, these PJIs often involve bacteria growing in a composite of cellular and extracellular matrix material complex, known as biofilms [2,3]. The exact location or predilection of biofilm growth on specific prosthetic components or materials remains an important, albeit understudied, question. There is no evidence in the literature that has mapped biofilm formation to one specific material type or location or demonstrated mapping's importance in management of implant related infections.

Previous research examining the role of biofilms in PJI virulence is primarily focused on detection methods, imaging modalities and bacterial classification. While mapping to particular components is not commonly a primary focus, some work has examined patterns of bacterial formation that offer preliminary insight. Stoodley et al. [4] have shown that colored fluorescent proteins can be expressed to directly observe *Pseudomonas aeruginosa* biofilms on 316L stainless steel screws. Patchy development was noted on screw shafts and between the threads of several screws, with no significant pattern of development noted.

Confocal laser scanning microscopy has also been shown to aid in biofilm visualization on implant materials and surrounding tissue [5]; however, focused analysis does not exist regarding mapping or preferential formation of the biofilm on specific components or anatomic regions. Kobayashi et al. [6] and Nguyen et al. [7] have demonstrated the utility of ultra-sonication in detection of biofilms in PJI cases, showing that brief exposure of one to five minutes of infected components to ultra-sonication is effective in detecting bacterial adherence. However, few components were shown to harbor bacteria and those that did were not examined for anatomic or component-specific variability. Preliminary work by Gómez-Barrena et al. [8] showed no significant difference between hip and knee components in harboring bacterial biofilm formation. While this work focused primarily on the pathogenesis of various microorganisms and only classified components as "hip" or "knee," the finding that component type did not affect adherence shows primary indications that mapping biofilm formation may not be important to the management of PJIs. Existing research regarding biofilm mapping is not complete and cannot definitely define the importance of its practice. There is a need for additional work to replicate preliminary experiments and directly study the location of biofilm formation on orthopaedic components.

Another aspect of mapping to be considered is the material composition of orthopaedic components and the possible varying ability of such materials to harbor biofilm formation. Sheehan et al. compared stainless steel and titanium components using isolated strains of *Staphylococcus aureus* and *Staphylococcus epidermidis* in a femoral intramedullary implantation model in rabbits [9]. This study demonstrated higher levels of biofilm adherence to stainless steel components within the first 48 hours. Both strains showed this preferential growth, with higher levels of adherence reaching nearly 150% on stainless steel compared to titanium. Tuke et al. expanded the analysis of implant failure to analyze the potential role of metal-on-metal bearing surfaces [10]. A wear patch was noted to form on retrieved failed devices, indicating a potential loosening of the orthopaedic components and opportunity for colonization. These studies demonstrate the possibility of material-specific variation in biofilm formation that may allow for mapping. It appears possible that specific components, due to their composition or anatomical position, may be more susceptible to bacterial colonization with strains associated with PJI. However, there is a lack of evidence regarding materials commonly used in implant devices, with only preliminary and speculative data suggesting variation that may lead to improved surgical management.

Given the limited number of studies evaluating the location of biofilms on specific components isolated from PJI patients, either clinically or in the laboratory, we conclude that there is no strong evidence that biofilm formation favors either a specific location or material type in total joint arthroplasty. Anecdotally, it seems intuitive that knowledge of biofilm location would aid in surgical therapy, and a recent paper argues that an orthopaedic biofilm disclosing solution used intraoperatively would be a useful surgical tool [11]. However, the lack of evidence in the literature prevents the conclusion that mapping biofilms to a particular component is of clinical relevance.

Disruption

Authors: Alex McLaren, Garth D. Ehrlich

QUESTION 1: Is there evidence that interference with bacterial communication by blocking quorum sensing molecules can minimize biofilm formation in vivo?

RESPONSE: In vivo animal studies have demonstrated that interference with quorum sensing signals/molecules in some infections leads to decreased biofilm formation. There are contradictory results in *Staphylococcus* species. However, there are no clinical studies demonstrating this phenomenon.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

PRE-MEETING RATIONALE

While there is extensive in vitro and in silica work being done and reported on quorum sensing and anti-quorum sensing molecules, otherwise known as quorum quenching, there are limited in vivo data and none of the anti-quorum sensing strategies are ready for widespread clinical application. Based on a search of the NCBI, Embase and Scopus databases, there are seven in vivo investigations that were reported during the last five years [1–7] (Table 1). In addition, there have been reports of quorum sensing inhibitor

TABLE 1. Seven in vivo studies over the last five years

Study #	Animal Model	Agent	Mechanism	Clinical Effect
1 [1]	Medaka fish peritoneal catheter infection	3-Phenyllactic Acid (PLA)	Antagonistically binds to quorum sensing receptors RhIR and RqsR, blocking initial attachment of Pseudomonas aeruginosa (PAo1) thereby delaying biofilm formation [1]	Decreased biofilm formation
2 [7]	Wistar rat pyelonephritis	phytol	Down regulate offimA, fimC, flhC, flhD, bsmB, pigP shlA genes in S. marcescens leading to decreased biofilm formation and virulence factor production	Decreased bacterial counts and virulence enzymes (lipase and protease) decreased inflammatory markers (MDA, NO, MPO) and histologically no acute inflammation
3 [2]	Mouse gingivitis	Quorum Sensing Inhibitors (furane compunds, d-ribose)	Interfere with AutoInducer-2	Decreased colony counts and alveolar bone loss
4 [4]	Round worm survival (Caenorhabditis elegans)	Sub-inhibitory concentration of ceftazidime	Inhibition of QS regulated virulence traits and biofilm formation; binds to the las and pqs QS receptors in P. aeruginosa	Increased survival
5 [5]		Acylase	Degrades Quorum sensing peptides	Delay biofilm formation for S. aureus and P. aeruginosa for up to 7 days
6 [6]	Larval oyster mortality	Phaeobacter gallaeciensis S4Sm	Down regulate pathogen virulence genes	Decreased mortality from V. tubiashii infection
7 [3]	Round worm survival (Caenorhabditis elegans)	Pyrrolo (1,2-a) pyrazine-1,4-dione, hexahydro-3-(2-methylpropyl) from Alcaligenes faecalis	Modulate expression of quorum sensing (QS) regulators luxT and lafK	Increased survival from V. alginolyticus infection

and quorum quenching studies presented at scientific meetings utilizing multiple in vivo models [8].

The experimental strategy varies. In vitro data are relied upon to identify the molecular mechanism leading to interference with quorum sensing that causes decreased biofilm formation, whether it be blocking the signaling peptide production, blocking receptors or active initiation an antagonist signals by the agent. The in vivo data confirm that the agent decreases biofilm formation.

QUESTION 2: Can a biomaterial surface be modified to dispel bacterial adherence and biofilms? What are the potential concerns in modifying implant surfaces to combat biofilms?

RESPONSE: The purpose of the surface modification is to decrease perioperative bacterial adherence and thus prevent biofilm formation. This has been shown in in vitro studies and in vivo animal models. There have been numerous strategies devised to alter surfaces. Such modified surfaces may interfere with the expected osseointegration, mechanical stability and long-term implant survivability. The duration of long-term anti-infective effects are unknown. To date, no positive in vitro effect has been translated into a clinical setting.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

PRE-MEETING RATIONALE

Periprosthetic joint infections (PJI) represent 1-20% of the failure mechanisms in total joint arthroplasty leading to significant morbidity and mortality [1–3]. The material surface used for implantation is a significant factor in bacterial colonization leading to PJI [4,5]. Some surfaces are more prone to bacterial adherence and formation of biofilms. A biofilm is an aggregate of microbial cells that are irreversibly associated with a surface and encapsulated in a complex polysaccharide "slime" extracellular matrix that may include enzymes, crystals and glycoproteins - together forming a living tissue [6,7]. The most common microorganisms residing in biofilms are *Staphylococcus S.* species [8,9]. The bacteria in biofilms take either sessile forms on metal, bone fragments and cement; or planktonic forms that can disperse as clumps within the joint fluid [10,11]. Due to such complexity of form, material and function, the question remains whether modified implant surfaces can play an anti-infective role and what are the main concerns with modifying biomedical devices.

Can a Biomaterial Surface Be Modified to Dispel Bacterial Adherence and Biofilm?

In 1987, Anthony Gristina [12] was the first to propose the concept of a race for the surface, wherein the fate of the biomaterial implant is dependent on a balance between tissue integration and microbial adhesion with biofilm formation. This concept sets the hypothesis that material modifications that improve osseointegraion while inhibiting bacterial adhesion would provide a theoretical advantage and eliminate the risk of infection [13]. As a result, there is a wide array of anti-infective surfaces proposed for utilization in orthopaedic implant applications.

Gallo et al. [14] summarized the available options as bactericidal, anti-adhesion surfaces, multifunctional/smart coatings and alternative materials.

Romanò et al. [15] propose a newer classification regime that describes antibacterial coating under three distinctive groups [1]:

1. *Passive surface finishing/modification* Surfaces that prevent adhesion without releasing anti-bacterial substances.
2. *Active surface finishing/modification* Surfaces that release anti-bacterial substances.
3. *Perioperative antibacterial carriers or coatings* Carriers or coatings applied during surgery that are antibacterial and either biodegradable or non-biodegradable.

Active surfaces and perioperative coatings provide only temporary solutions while they exhaust their antimicrobials in time. Passive surfaces may not provide the necessary bactericidal properties needed to eliminate the infection while their action is limited to the immediate peri-implant area. The ideal implant surface should have: (1) a strong anti-infective potential, (2) long duration of effect, (3) biocompatibility with mechanical construct and stability and (4) minimal host response and harm [16–18]. To achieve that, surfaces

TABLE 1. Proposed anti-infective surfaces for utilization in orthopaedic implant applications

Method	Type	Examples
Bactericidal	Inorganic	Ag, AgNP, AuNP, TiO2, Se, CuNP
	Organic	Coated or covalently linked antibiotics, chitosan derivatives
	Combined	Multilayer coating, positively charged polymers
	Other	Non-antibiotic (peptides, enzymes, oils)
Anti-adhesion		Anti-adhesive polymers
Multifunctional/smart coating	Passive	Nanostructured "smart" materials
	Active	Sensors conjoined to nanocontainers
Alternatives		Lytic bacteriophages

Ag, silver; NP, nanoparticles; TiO2, titanium oxide; Se, selenium; Cu, copper

can be physically and mechanically prepared and coated or chemically modified.

The early reversible adhesion stage of bacteria to titanium is largely influenced by the topographical features on the surface [19]. Several anti-adherent coatings on titanium have been created by surface modification with polymers, copolymers or proteins. Del Curto et al. [20] has shown that the crystalline phase of titanium oxide on the surface of biomaterials reduced bacterial attachment without adverse effects on the biocompatibility. Ferraris et al. [21] showed that mechanically produced nanogrooves (0.1-0.2 um) and keratin nanofibers can increase biocompatibility without increasing bacterial adhesion. Lorenzetti et al. [19] has applied hydrothermic treatment methods to similarly achieve decreased bacterial adhesion. This data is very encouraging and supports the concept that biomaterial surfaces can be modified to dispel bacterial adherence.

Silver (Ag) has been known throughout history not only for its jewelry applications but for its antimicrobial effects [22,23]. The mechanism of action is thought to be the formation of reactive oxygen species and biologically active ions that damage bacterial walls and bind to nucleic acids and interrupt bacterial replication [24]. An added advantage of Ag usage is the effect against surface-adhered bacteria without significant drug-resistance [25,26]. Harrasser et al. [27] studied the antimicrobial effects of Ag and has observed significant antimicrobial activity that was positively correlated with Ag concentrations. A recent study by Aurore et al. [28] indicated that Ag nanoparticles (AgNPs) enhanced the bactericidal activity in osteoclasts.

As such, AgNPs have gained attention for their application on implant surfaces due to their anti-biofilm potential, wide-spectrum antimicrobial properties and low cytotoxicity to human cells [18,22,29–33]. There is an abundance of literature that examine the anti-biofilm effect of AgNPs [18,25,34]. Kalishwaralal et al. [35] demonstrated that AgNPs at a concentration of 100 nM almost entirely inhibited biofilm formation (> 95%) from *S. epidermidis* and *Pseudomonas aeruginosa*. Slane et al. [33] found that bone cements impregnated with AgNPs significantly reduced biofilm formation compared to standard cement. Some studies have also mentioned the synergistic effect of AgNPs with antibiotics [36–38]. The most notable advantage of AgNP-coated surfaces is the ability to exhibit a continuously controlled-release of active agents to the periprosthetic region for a substantial period of time, thus working at both the surface layer but also in the immediate environment.

Recently, iodine has been shown to be a successful adjuvant for irrigation and debridement in cases of PJI [39]. Adapting this idea to implant surfacers, Tsuchiya et al. [40] report on a clinical study of more than 222 patients in whom iodine surface treated implants were very effective for preventing and treating infections after orthopaedic surgery. No clear cytotoxicity or adverse effects were observed. Shirai et al. [41] similarly demonstrated a significant reduction in pin tract infection rate by using iodine surface-treated insertion pins and external fixators. Kabata et al. [42] also show that iodine treated hip implants remained free of infection in 14 revision cases for infection and in 16 immunosuppressed primary total hip arthroplasties. No issues related to local and systemic toxicity or impaired osteoconductivity and bone bonding have been reported in any of these studies.

Similar to Ag and iodine, multiple studies have targeted incorporation of antibiotics into surface coatings directly deposited onto the implant [43–45]. Most of these applications build on the information learned from antibiotic-laden bone cements and provide an initial protective barrier for infection [46–48]. Current protocols include hydrogels, poly-D, L-lactide, calcium phosphate or carbonated hydroxyapatite antibiotic coatings. Other direct techniques attempt to physically modify the surface for antibiotic adsorption, or simply dip the implant in antibiotics producing a transient coating [48–50]. Recent scientific progress in biomolecular interactions and nanoscale engineering provides new inspiration for medical implant designs that may have the potential to deal with infection [51,52]. Antibiotics covalently linked to metallic surfaces have been shown to inhibit bacterial colonization both in vitro and in vivo [13,53,54]. Despite all progress, most systems are rudimentary and difficult to scale up to industry standards; further research and a smarter implant technology is necessary. Such technology should directly integrate biological defenses in the implant design, making protection feasible for the life of the replacement prosthesis.

What Are the Main Problems in Modifying Implant Surfaces in the Fight Against Biofilms?

One of the main concerns of antimicrobial biomaterials is the possible cytotoxic effect of the surface modification as related to osseointegration and implant survival in vivo. Based on a preliminary literature review, only four laboratory studies [55–58] and one clinical study [59] reported the side effects of surface modification. Ag surface modifications have shown higher lactate dehydrogenase (LDH) activity as a marker of cell death, as well as lower cell count and alkaline phosphatase (ALP) activity [55–58]. Nevertheless, such

effects are hard to correlate with clinical outcomes. Glehr et al. [59] performed the only clinical study that focused on Ag while examining its use in mega-prosthesis. They have documented the presence of heavy metal poisoning symptoms, even though no correlation with the blood Ag concentration was observed. Another two in vitro studies used zinc and farnesol (anti-fungi medicine) surface modifications respectively. The results showed lower ALP activity as well as pre-osteoblastic cell damage. Multiple studies thus agree that AgNPs have the potential to be toxic to many cell types in a dose- and time-dependent manner, especially when inhaled, injected or ingested [60–62]. Interestingly, Shen et al. [63] conducted a study which revealed that both cobalt chrome alloys and pure titanium had cytotoxic effects to osteogenic precursor cells and mesenchymal stem cells, while the incorporation of AgNPs reduced this cytotoxicity.

When working with modified surfaces, bacteria can ultimately adapt and develop resistance to the agent used. Antibiotic resistance is an everyday occurrence in clinical practice. Bacteria have also been shown to surmount resistance to the ionic form of Ag, and less commonly, to AgNPs [64,65]. This is because prolonged exposure to AgNPs, unlike Ag ions, is less likely to result in resistance genes, since AgNPs have broad-spectrum capabilities by targeting multiple sites on or within bacterial cells [66]. Nevertheless, resistance to silver seems to be a slow process and is a less of a problem compared to antibiotic resistance [67]. Concerning though, Kaweeteerawat et al. [68] suggest that AgNPs could potentially enhance bacterial resistance to antibiotics through promoting stress tolerance by induction of intracellular reactive oxygen species causing DNA mutations.

In conclusion, bacterial biofilms are difficult for antimicrobial agents to penetrate. Preventing biofilms and bacterial adherence is probably the only effective way to address the problem of PJI. AgNPs and iodine are gaining increasing popularity especially for their anti-adhesion, anti-infective, and minimal bacterial resistance properties. Nevertheless, further investigation of the long-term outcomes of patients with modified surfaced implants is warranted.

QUESTION 3: What is the relevance of minimum inhibitory concentration (MIC) of infecting organisms in biofilm-mediated chronic infection?

RESPONSE: The use of MIC is limited to (1) defining antibiotics that the microorganism is susceptible to in its planktonic state but cannot be used to guide treatment of biofilm-based bacteria and (2) selecting long-term suppressive antibiotic regimens where eradication of infection is not anticipated. Alternative measures of antibiotic efficacy specifically in the context of biofilm-associated infection should be developed and validated.

LEVEL OF EVIDENCE: Strong

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

PRE-MEETING RATIONALE

MICs are used to define an individual microorganism's (hereafter limited to bacteria) susceptibility to a distinct array of antibiotics. Established methodologies for determining MICs relate to the planktonic state of the bacteria but not to biofilm-indwelling bacteria [1].

The majority of information relating to susceptibility testing and biofilm-indwelling bacteria originates from research in Cystic Fibrosis [2]. In relation to implant-associated biofilm infections, central venous catheters and urinary tract catheters are often investigated, but little clinical research has been performed in orthopaedic implant-associated biofilm infections [2,3].

As early as 1990, Anwar and Costerton identified the need for an extreme increase in in vitro concentrations of antibiotics, to which the planktonic bacteria were fully susceptible, when treating biofilm-indwelling bacteria [4,5]. In a review by key-opinion leaders on the topic of antimicrobial susceptibility testing in biofilm-indwelling

bacteria, it was noted that MIC is not suitable in predicting the effect of an antibiotic for a biofilm infection [6]. In the 2014 European Society for Clinical Microbiology and Infectious Diseases guidelines for the diagnosis and treatment of biofilms infections, it is noted that antibiotic susceptibility determination by MIC offers no guide to clinicians in the treatment of biofilms [7]. Rather than MICs, clinicians may need to rely on other measures of antibiotic efficacy, such as minimum biofilm eradication concentration (MBEC), minimum biofilm bactericidal concentration (MBBC) or minimum biofilm inhibitory concentration (MBIC). These are likely to be 100-1000 times the MIC, but the associated breakpoints that would permit reliable prediction of treatment success have not yet been established.

Theoretical mechanisms driving the high-level of resistance to antibiotics in biofilm include both the mechanical exclusion of antibiotic molecules by the polysaccharide matrix and the presence of dormant persister organisms within the biofilm. The relative contribution of each of these mechanisms is uncertain, but emerging data suggest that persister organisms constitute up to 10% of biofilm. Due to the adapted phenotype, they are able to evade the antimicrobial action of a variety of conventional antibiotics that rely on disruption of cell processes for their efficacy. Post et al. showed that, although it was possible to eradicate biofilm caused by *Staphylococcus aureus* (*S. aureus*), the necessary time-concentration profile could not be achieved in vivo by systemic administration or by any local delivery vehicles currently available [8]. Urish et al. concluded that tolerance was primarily a phenotypic phenomenon as increasing cefazolin exposure did not result in changes in MIC [9].

In two studies, Antunes et al. identified that among biofilm-indwelling Staphylococcus species isolates, 89% were considered to be clinical resistant to vancomycin, even when the same isolates all presented MIC values categorizing the isolates as fully susceptible to vancomycin (MIC </= 2μg/mL) [10,11]. The authors concluded that this particular observation showed "that biofilm production results in an important barrier to antimicrobial diffusion into the biofilm" and that "antimicrobial susceptibility testing based on MIC values alone cannot accurately determine the exact susceptibility of bacterial biofilms."

Ray et al. tested ceftriaxone and gentamicin, both commonly used antibiotics in orthopaedic surgery, against *Serratia marcescens* biofilm in vitro at doses of 10, 100, 1,000 times that of the established MIC for the planktonic isolate and found that the antibiotic, even at these concentrations, did not reduce biofilm biomass [12].

Reiter et al. tested rifampicin and vancomycin against methicillin-resistant *S. aureus* planktonic and biofilm isolates in vitro and found 32-32,000 times increase in resistance for rifampicin and 8-512 times increase in resistance for vancomycin in biofilm isolates [13]. They subsequently concluded that the tested antibiotic were not able to eradicate mature biofilm at the concentrations needed for planktonic microbes (the MIC).

Ruppen et al. tested gentamicin as an adjuvant to penicillin in *Group B Streptococcus* biofilm in vitro, and found a 2,000-4,000 times increase in resistance for penicillin in the presence of biofilm and 1-4 times increase for gentamicin [14]. The authors noted that the gentamicin doses tested did not correlate with achievable in vivo concentrations. The authors concluded that the MIC did not correlate to the susceptibility to the tested biofilm strains.

Hajdu et al. tested an array of antibiotics against *Staphylococcus epidermidis* biofilm in vitro. The planktonic bacteria susceptibilities were tested to all antibiotics in the study. When biofilm-indwelling bacteria was tested, susceptibilities were up to 128-times the established MIC. Only ceftriaxone showed a minor reduction in total biofilm biomass. No eradication occurred for any antibiotics at any level above MIC; it was also noted that these levels were much higher than any clinical in vivo achievable concentration [15].

Ravn et al. tested dislodged biofilm from in vitro implant infections of *S. aureus*, *Staphylococcus epidermidis*, *Escherichia coli* and *Cutibacterium acnes* and found antimicrobial susceptibility to be identified at 4 times that of MIC (for *Escherichia coli* and ciprofloxacin) to 1.024 times that of MIC (for staphylococcus species + *Cutibacterium acnes* and vancomycin) [16]. The authors concluded that MIC correlation to in vivo values may not affect biofilm-indwelling bacteria.

Monzón et al. tested *Staphylococcus epidermidis* biofilm susceptibility on an array of antibiotics in vitro. All the isolates tested were fully susceptible to vancomycin in their planktonic form. The authors found that vancomycin, teicoplanin, clindamycin and oxifloxacin at MIC had a low killing rate in 24-hour mature biofilm. Rifampicin was not affected by the presence of mature biofilm and remained with a high killing rate at MIC [17]. The authors concluded that antibiotics may lose their killing ability in mature biofilm at clinical relevant in vivo levels, despite being fully susceptible at MIC.

Molina-Manso at el. tested susceptibility of Staphylococcus species biofilm in vitro and found that none of the tested antibiotics (including rifampicin, vancomycin, clindamycin, cloxacillin, ciprofloxacin) could eradicate the biofilm-indwelling bacteria, even at concentrations highly above the established MIC for the individual isolates [18].

Claessens et al. tested the effect of antibiotic concentration at up to 40 times the established MIC of the individual isolates in *Staphylococcus epidermidis* biofilm in vitro and found that only rifampicin could decrease but not eradicate the biofilm mass, whereas vancomycin, teicoplanin and oxacillin did not decrease the biofilm mass [19].

Given the plethora of evidence detailed above, there is a clear need to seek alternative approaches to the prevention and treatment of biofilm related infections. The use of local antibiotic delivery systems is widely regarded as a possible means to achieve sufficiently high concentrations of antibiotic to exceed the MBEC. However, there is little guidance on the optimal duration that MBEC should be exceeded to affect a cure. There is also concern that, although early elution of antibiotic from cement produces high local concentrations of antibiotics, late sub-MIC concentration may promote the development of antibiotic resistance, particularly amongst persister populations. Furthermore, the MBEC may well change with time of exposure to antimicrobials further complicating the determinants of optimal local dosage and carrier systems [20].

QUESTION 4: What is the minimum biofilm eradication concentration (MBEC) of anti-infective agents?

RESPONSE/RECOMMENDATION: The MBEC of antimicrobial agents is a measure of in vitro antibiotic susceptibility of biofilm producing infective organisms. It is dependent on the surface, medium and the exposure period to an antimicrobial agent. There are no standardized measurement parameters for MBEC. MBEC is currently a research laboratory value and lacks clinical availability. In the group's opinion, there is value in developing a clinically-validated MBEC assay.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

PRE-MEETING RATIONALE

A Medline query on the item "minimum biofilm eradication concentration" retrieved 149 references. For the most part, these references relate to bacteria with little or no involvement in infection on orthopaedic devices. A query about "minimum biofilm eradication concentration of infective agents" retrieved 18 references; none of them clearly related to bone infection on material. The Medline request "minimum biofilm eradication concentration and implant associated infection" retrieves only three references [1–3].

The work of Coraça-Huber et al. [1] focuses on the evaluation of a study model of the minimum bacterial concentration (MBC) in infections on material, using strains of *Staphylococcus aureus (S. aureus)* and collection *Staphylococcus epidermidis (S. epidermids)*. Biofilm formation is supported by Innovotech, Inc.'s MBEC-HTP (high throughput plates) system (Edmonton, Alberta, Canada). The formation of biofilm is documented by electron microscopic study. The comparison of the minimum inhibitory concentration (MIC) and MBEC was made in this model for daptomycin, gentamicin, vancomycin, rifampicin, fosfomycin, clindamycin and linezolide. Biofilms generated by *S. epidermidis* show less resistance to antibiotics than those generated by *S. aureus*. The MBEC is much higher than the MIC of all antibiotics. Daptomycin and rifampicin are the most effective antibiotics against *S. aureus* embedded within a biofilm without obtaining their complete eradication.

Brady et al. [2] raised a question about the validity of the MBEC to replace the IJC in situations of infection on equipment. Twenty staphylococcal isolates from catheter infections were studied (17 CNS, 3 MSSA) and ten antibiotics were tested (penicillin, oxacillin, erythromycin, clindamycin, fucidine, tetracycline, gentamicin, vancomycin, teicoplanin and ciprofloxacin). The quantification of biofilm formation on microtiter plates and Tryptic Soy Broth (TSB) is obtained by crystal violet method. Detection of the biofilm formation mechanism (protein or polysaccharide) is obtained by treatment of sodium metaperiodate and protein kinase plates. The search for the ica operon (code in staphylococci for the production of enzymes necessary for adhesion) is done by polymerase chain reaction. Sixteen of the 20 strains (80%) tested produce biofilm; low for 8 strains, moderate for 2 strains, and high for 6 strains, all carriers of ica operons. The MBEC was 10 to 1,000 times higher than the MIC for bacteria producing biofilm. In practice, the MBC is > 256 µg/ml for all strains studied, whether or not biofilm production is proven by the techniques used, raising the question of strains forming a protein biofilm that cannot be quantified by the crystal violet method.

Zaborowska et al. [3] analyzed the sensitivity of staphylococci and enterococci from bone infections on material according to their biofilm production. The 13 strains studied were derived from infections on percutaneous bone anchoring material, on femoral amputation stumps for fitting. This technique involves a permanent protrusion of a titanium implant through the skin, a potential entry point for bacteria from the cutaneous and fecal flora. The bacteria studied were obtained from bone and material samples obtained from 11 infected patients. These are four strains of *S. aureus*, three strains of coagulase-negative staphylococci and six strains of *Enterococcus faecalis*. Ten antibiotics are tested in MIC and MBEC (clindamycin, gentamicin, vancomycin, linezolide, ciprofloxacin, oxacillin, fucidic acid, ampicillin, trimethoprim/sulfamethoxazole and rifampicin). The microtiter plate culture in TSB is used to evaluate the biofilm

production capacity of the bacteria analyzed. The total mass of the biofilm formed is measured by the crystal violet technique to determine a biofilm score (absent, low, moderate, high production). The production of exopolysaccharide (slime) is measured by the Congo red technique. The search for the ica operon for staphylococci is obtained by PCR test. The determination of the MBEC is obtained by the Calgary Biofilm Device (CBD). Eleven of the 13 strains studied produce biofilm, the quantity of biofilm is heterogeneous according to bacterial species. The MBEC is significantly higher than the MIC for the 10 antibiotics studied. The ratio MBEC/MIC is variable with marked differences between bacterial species. The MBEC is high and homogeneous for all strains of *Enterococcus faecalis*: MBEC/MIC from 64 to 2048, median 512, for vancomycin, ciprofloxacin, linezolide, ampicillin and rifampicin. In comparison, Staphylococcus strains show significant inter strain variability; for *S. aureus* MBEC/MIC ranges from 1 to 2048, median to 9, for the 10 antibiotics tested. For *S. epidermidis* the ratio ranges from 0.0038 to 64, median to 1. The ica operon is isolated for all staphylococci; however, two strains do not produce slime by referring to the Congo red technique, expressing variability in gene expression. For these two strains, the biofilm score assessed by the crystal violet method was strongly positive, indicating that this biofilm consisted mainly of aggregated cells without slime production.

The clinical follow-up of the 11 patients was correlated to the results expressed in MBEC. Failure was correlated with a high MBEC value without statistical evidence. Two patients did not present any complications (recurrence, reinfection or need for material removal). For one, the strain did not produce biofilm; for the other, biofilm production was low. For other strains with low to moderate biofilm production, patients experienced one or two complications. One patient developed all three complications and the infecting strain was highly biofilm producing.

Of these three studies, only Zaborowska et al.'s [3] corresponds to a clinical situation of infection on an orthopaedic device. As in the other two studies, the work presented here only tests antibiotics as monotherapy, whereas clinical use is readily with dual therapy, particularly when rifampicin is prescribed. The work of Saginur et al. [4] on 17 strains of *S. epidermidis*, 11 strains of methicillin-susceptible *Staphylococcus aureus* (MSSA) and 12 strains of methicillin-resistant *Staphylococcus aureus* (MRSA), isolated from infections on material tested in MIC and MBEC (CBD device) 9 antibiotics in monotherapy and 94 combinations of antibiotics in bi or tritherapy. The MBEC is significantly higher than the MIC, but a significant heterogeneity between strains is also found in monotherapy. Among the 94 antibiotic combinations tested, 11 are bactericidal on more than 90% of MSSA strains growing in biofilm and 9 are for *S. epidermidis*. Rifampicin is the antibiotic most often present in these combinations.

The efficacy of antibiotics against bacteria growing in a biofilm, is generally explored in vitro under standardized, brief conditions of exposure of the bacterial strain to the antibiotic tested. In clinical practice, exposure to antibiotics is prolonged [5]. In this work, bacterial strains (MSSA, MRSA, *S. epidermidis*, *E. coli*, *Pseudomonas aeruginosa*) are tested for growth in a biofilm at varying antibiotic concentrations for three antibiotic exposure durations of one, three and five days. For most strains and antibiotics tested, the MBEC is significantly lower after 5 days of exposure to antibiotics than that measured after 24 hours of exposure.

It is commonly accepted that bacterial adhesion and bacterial growth within a biofilm, are the determinants of infection on material. It is also commonly accepted that the effectiveness of antibiotics within a biofilm is greatly diminished. Measurement of in vitro antibiotic activity by the MIC determined on planktonic bacteria is not predictive of in vivo antibiotic activity on bacteria growing in a biofilm. The MBEC is the supposedly most appropriate parameter for predicting the efficacy of antibiotics in vivo. The literature review shows that this parameter is over the last few years increasingly studied and taken into account to test antibiotics or various molecules against multiple microorganisms.

While the in vitro MBEC determination method itself is not problematic, the measurement of biofilm production is more random. Biofilm is made up of both bacterial cells and a substance of either a polysaccharide (slime) or protein nature. Not all bacteria produce biofilm. For staphylococci, the production of biofilm is linked to the existence of an operon (ica), detectable by PCR but whose expression is variable, and the highlighting of the operon does not mean slime production. The measurement of the overall mass of biofilm, generally by the crystal violet technique, which potentially defines biofilm scores (absent, weak, moderate, strong), does not necessarily account for the composition of this biofilm, likely to modify the MBC of antibiotics.

The capacity to produce biofilm is heterogeneous depending on the bacterial species. On the available data, the capacity to produce biofilm is strong for *Enterococcus faecalis* without inter-strain variability. For staphylococci, the capacity to produce biofilm seems more marked in *Staphylococcus aureus* than in staphylococcus epidermidis, but inter-strain variability is important for staphylococci. Rifampicin appears to be a more active antibiotic in biofilm than average. However, the rule is by no means absolute. The efficacy of antibiotic combinations is significantly superior to that of monotherapy molecules.

In a clinical situation, for a given strain, the MBEC cannot be estimated a priori, at least for staphylococci. Of the few published data, the MBEC still appears to be higher than at least 64 times the MIC for antibiotics active against *Enterococcus fecalis* (ampicillin, vancomycin, linezolide, rifampicin). For other bacteria, the MBEC of active antibiotics is not known.

There is no antibiotic combination that guarantees bacterial eradication in the biofilm for a given strain of staphylococcus, although antibiotic combinations are generally more effective than monotherapy treatments. The in vitro measurement of the MBEC is not a routine use for the moment. The research field needs to define a standardized methodology for possible use in clinical practice. High biofilm production appears to correlate with a higher complication or failure rate than low or absent biofilm production without statistical demonstration at this time.

QUESTION 5: Do bacteriophages have a role in treating multidrug-resistant periprosthetic joint infection (PJI)?

RESPONSE: Unknown. Although some preclinical and clinical studies have demonstrated a good safety profile as well as promising therapeutic effects using bacteriophages for treating bone and joint infections, further clinical research using bacteriophage therapy in patients with multidrug-resistant PJI is required.

There are known obstacles to bacteriophage therapy, including the fact that bacteriophages are neutralized in serum and relevant pathogens contain Clustered Regularly Interspaced Short Palindromic Repeats - associated protein-9 nuclease (CRISPR/cas9) immunity against bacteriophage. Phages are usually bacterial strain specific; thus, a cocktail of different bacteriophage lineages may be necessary to effectively treat biofilm-mediated infections.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 100%, Disagree: 0%, Abstain: 0% (Unanimous, Strongest Consensus)

PRE-MEETING RATIONALE

PJI represent serious issues for patients worldwide. The surfaces of orthopaedic implants are all susceptible to colonization by biofilm-forming bacteria, such as methicillin-resistant *Staphylococcus aureus* (*S. aureus*) (MRSA), *Pseudomonas aeruginosa* (*P. aeruginosa*) and numerous other organisms, whose presence has been reported to play a key role in the occurrence of PJI, thus leading to antibiotic resistance [1–4]. To overcome these problems novel treatment strategies focusing on disrupting biofilms are being developed [5]. Utilization of lytic bacteriophages to eradicate bacteria causing biofilms is one of the promising emerging technologies [3,6].

Bacteriophages are natural viruses that infect bacteria. They are one of the most abundant organisms in the biosphere. Each bacteriophage is specific to a particular microbial species. Like all viruses, phages are only able to replicate inside their host cells. Lytic phages inject their genetic material into the host bacterial cell, cause bacterial cell lysis that liberates subsequent new phage particles. These new particles allow successive infection of additional bacteria in a rapid and exponential pattern, facilitating the complete eradication of the bacteria. The French microbiologist Felix d'Herelle first described bacteriophages in 1917 [7]. By their nature, bacteriophages are good candidates for antibacterial therapy. Indeed, they target a bacterium specifically, as long as the corresponding host bacteria is present. In comparison with antibiotics, this phenomenon is unique as it is exponential and self-sustained after a single or a few administrations. Moreover, lytic bacteriophages do not affect eukaryotic cells and not impact the gut microbiota when administered locally.

Bacteriophage technology is particularly promising in patients with multidrug-resistant PJI as: (i) multidrug-resistant PJI are becoming more and more frequent [8,9]; (ii) the rate of relapse is particularly high in patients with PJI caused by multidrug-resistant pathogen [9–11]; (iii) bacteriophages and antibiotics are synergistic [12,13]; (iv) there is no cross-resistance between antibiotic resistance and bacteriophage resistance [6–12]; (v) some in vitro and animal models demonstrated that bacteriophages could have an anti-biofilm activity [6,13,14]; and (vi) recent human and animal trials using phage therapy have not shown any local tissue toxicity or any adverse effects to the host [15–20].

Bacteriophages were used in the 1970s in France [21] and remained a popular treatment throughout the 20th century in Eastern Europe (Poland) and the former Soviet Union (Georgia, Russia) in patients with relapsing osteomyelitis. Few case series have been published in the literature, including patients with pyogenic native joint infection, chronic osteomyelitis, suppuration after bone fracture and diabetic foot osteomyelitis [22–26].

In preclinical studies using animal models for PJI bacteriophages were found to prevent bacterial adhesion and also effectively disrupt the formation of biofilm [13,27]. Animal studies also have proven synergism between antibiotics and bacteriophages [13]. In another animal study, Kishor et al. [26] studied the efficacy of several phages used in conjunction as a treatment modality for chronic osteomyelitis caused by MRSA in rabbits. The study showed that the combination of specific phages selected based on their virulence against various clinical MRSA strains was effective in eradicating the infection, thus suggesting that a "tailor-made cocktail" of phages can alone be effective in targeting specific bacteria in the setting of a chronic infection. Some of the issues with current PJI animal models are that they don't replicate mechanical stresses occurring in clinical settings and, therefore, may not be fully representative of clinical situations.

Wright et al. conducted a randomized, double-blind clinical trial using bacteriophages in humans [28]. They studied the effect of the combination cocktail of six phages targeting *P. aeruginosa* in the treatment of antibiotic-resistant chronic otitis media infection. The authors achieved measurable therapeutic effects with minimal dosing, thus suggesting a promising role for phage therapy in treating antibiotic-resistant infections.

No case series including patients with PJI has been published (we retrieved only two cases from a French series of bone and joint infection treated with bacteriophages) [6]. In the Georgian practice, specific phages mixtures are used, such as the "pyophage" cocktail that contains phages against *S. aureus*, *Streptococcus*, *Proteus*, *P. aeruginosa* and *Escherichia coli* (*E. coli*) or specific bacteriophages targeting specifically staphylococci, as the Sb-1 phage (that could be imported in the USA), the bacteriophage K or the bacteriophage ISP [22]. In Poland, phage(s) are selected from a bank based on their activity on the patient's strain to adapt the treatment (personal medicine) and to ensure antibacterial activity of phages used [23,24]. All these bacteriophages are classically prepared with a bacterial inoculum, in vitro infection with the bacteriophage and purification of the preparation in aliquots at 10^7 to 10^8 PFU/mL. These preparations are approved by local authorities but do not respect European "good manufacturing practice" (GMP) standards for conducting clinical trials and targeting Market Authorizations (MA). Indeed, the final product requires total elimination of bacterial components that are

generated during the production process, such as toxins, in order to limit pyrogenicity and adverse events that may arise during phage administration/use, especially when the phage is administered intravenously or directly in a joint cavity. As a consequence, bacteriophages are currently not injected directly into the joint in patients with PJI but locally throughout the fistula and/or orally in patients with chronic osteomyelitis [23–25].

Recently, an European multicentric clinical trial evaluating phage therapy of burn wound infections has been done using *P. aeruginosa* and *E. coli* bacteriophages from a GMP French bioproduction process that was implemented according to European Medicine Agency standards (ClinicalTrials.gov Identifier: NCT02116010). The French team from the Lyon bone joint infection (BJI) study group (also called CRIOAc Lyon, a regional reference center for the treatment of complex bone and joint infection in France; http://www.crioac-lyon.fr) has treated as salvage therapy, under the supervision of the French health authorities, three patients with chronic bone and joint infection (one osteomyelitis due to extensively drug-resistant *P. aeruginosa*; and two *S. aureus* PJI) with bacteriophages that follows the same process of production. For all the patients, the cocktail was personalized and selected based on the bacteriophage susceptibility of the clinical isolates (phagogram; similar principle as antibiogram but with bacteriophages) that was isolated after a joint puncture before the surgery. The two patients with PJI had chronic infection with purulent discharge and were treated with debridement antibiotics and implant retention (DAIR) supplemented with a direct administration of the bacteriophage *S. aureus* cocktail in the joint cavity at the end of the procedure. Both patients are doing well during the follow-up of 12 months and 3 months, respectively (unpublished data). A randomized clinical trial called PHAGOS will start soon in France, to evaluate the addition of *S. aureus* bacteriophage in patients with relapsing *S. aureus* PJI. The availability of *P. aeruginosa*, *E. coli* and *S. aureus* with GMP standard in France is a great opportunity to evaluate the phage therapy as an additive treatment in patients with PJI, especially in patients with multidrug-resistant PJI.

Although phage treatment looks promising and safe, further research is needed to understand immunogenicity and answer the remaining questions related to treatment by phage such as timing, duration, methods of delivery and route of administration. Limitations of present studies include the reduced spectrum of bacteria tested, which are limited to MRSA and *P. aeruginosa*, without considering coagulase-negative staphylococci (CoNS), which substantially contribute to PJI onset [29]. In addition to these there is a concern with regards to the immunogenicity of phages and resulting diminished therapeutic efficacy [30].

QUESTION 1: Are pediatric patients on oral or intravenous steroids at an increased risk of developing septic arthritis?

RECOMMENDATION: Unknown. There is no definitive link between the use of oral or intravenous steroids and development of septic arthritis in pediatric patients.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 86%, Disagree: 5%, Abstain: 9% (Super Majority, Strong Consensus)

RATIONALE

Septic arthritis is an infection of joints that spreads through systemic or local bacterial, viral or fungal infection. The overall prevalence of septic arthritis is relatively higher among children who are less than 4 years old. The incidence of septic arthritis has been reported to be 10 cases per 100,000 population and as high as 20 to 70 cases per 100,000 in patients with rheumatoid arthritis in the USA. The disease usually spreads through hematogenous system mainly due to intravenous drug use or prolonged use of a catheter and low immunity. The most common predisposing conditions that can develop into septic arthritis are rheumatoid arthritis, gout or osteoarthritis. In children, the hip is most commonly affected joint by septic arthritis as compared to the knee in adults accounting for 50% cases.

Computerized research of databases (PubMed, Medline Ovid and Google Scholar) was used for the literature review from 1950 to 2018. The shortage of literature could not directly link IV or oral steroid therapy as a risk factor for children to develop septic arthritis as an adverse reaction. Many randomized clinical trials were, however, found to be in favor of the prolonged use of IV and oral corticosteroid to avoid complications in pediatric patients suffering from septic arthritis and no further complications were observed that lead to the worsening of this disease [1–3]. There is still a debate whether immunosuppressive drugs, such as corticosteroids and cytotoxic agents, increase the risk for septic arthritis [4]. The potential association between administration of steroids and septic arthritis may be explained by the fact that steroids reduce the body's immunity and ability to fight infection [4]. One of the indirect causes of septic arthritis was found to be iatrogenic in 41.8% of adults, and the number of iatrogenic infections in Iceland increased from 2.8 cases/year in 1990–1994 to 9.0 cases/year in 1998–2002 ($p<0.01$) [5]. These iatrogenic infections can be linked to the use of unsterile intra-articular injections, possible use of contaminated needles or a break in the sterility during arthroscopic procedures [6,7].

The study conducted in the USA reported 32 cases of septic arthritis due to fungus-contaminated methylprednisolone vials [8]. However, these studies lacked proper evidence as these were descriptive in nature. These studies also did not fulfill our inclusion and exclusion criteria as it does not show a direct relationship of septic arthritis with steroid therapy rather than being an iatrogenic infection.

A case report published in 1957 reported septic arthritis as a reaction to steroid therapy in a woman who was 34 years old; she had been receiving corticotrophin, cortisone, hydrocortisone and prednisolone at various times in a year for the treatment of lupus erythematosus. A similar presentation was found in a man 54 years old suffering from exfoliative dermatitis and was getting treated with the same medicine. The steroid therapy resulted in septic arthritis of one knee and both hands including disfigurement of his fingers. Unfortunately, this study could not hold much evidence as it had a weak study design and the lowest number of reported cases. It also included adult patients so it cannot be generalized to children [9].

Diagnostic

Authors: Ali Parsa, Mahzad Javid

QUESTION 1: What are the essential tests that need to be done in pediatric patients with joint infections?

RECOMMENDATION: Essential laboratory tests include serum C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), white blood cell (WBC) count, blood cultures, synovial fluid analysis and culture of tissue and/or synovial fluid. Further molecular testing and leucocyte esterase (LE) testing may have a role and warrant further research. Imaging studies include ultrasound in the hip joint. Symptoms lasting over a week warrant investigation with plain radiography. Magnetic resonance imaging (MRI) and bone scanning may have value in confirmation of the diagnosis in some patients.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 88%, Disagree: 6%, Abstain: 6% (Super Majority, Strong Consensus)

RATIONALE

Diagnostic evaluation of children with suspected joint infection or osteomyelitis should include CRP, WBC count and ESR [1]. CRP is valuable as a negative predictive tool since CRP < 1.0 mg/dL helps rule out the diagnosis of septic arthritis (SA) with an accuracy of 87% [2].

Synovial fluid aspiration should be performed. Samples should be transported in a heparinized syringe or pediatric culture bottles to prevent the clotting and enumeration of leukocytes [3]. Cell count and differential, gram stain and culture of the obtained synovial fluid are important steps in diagnostic work up of pediatric patients with SA [4,5].

A wide range of organisms can cause SA in pediatric patients. Thus, culture samples should be sent for both aerobic and anaerobic cultures. If an infection with unusual organisms is suspected, then a specialized culture medium may need to be used. For example, SA caused by *Kingella kingae* may require the use of cell lysis culture bottles for isolation of the organism [3]. If there is clinical suspicion for infection by *Neissena gonorrhoeae;* rectal, oropharyngeal, urogenital cultures and urine deoxyribonucleic acid (DNA) analysis are indicated [6,7].

In infants and young children, subperiosteal needle aspiration can be performed if point tenderness exists [3]. Although a WBC count > 50,000-60,000/mm^3 is typically expected, a synovial fluid leukocyte density of 5,000-8,000 cells/mm^3 has been found in cases of pediatric SA [8].

Conventional radiographs of the affected joint should also be taken in pediatric patients as imaging may show signs of osteomyelitis [9–11]. Plain radiographs are typically normal [12]. Ultrasound evaluation of the affected joint has been reported to be useful in the diagnostic work-up of SA, especially of the hip [12]. In one study, normal hip ultrasound was found to have a negative predictive value of 100% for SA [13]. In some circumstances additional imaging may be needed. MRI is the cross-sectional imaging modality of choice in pediatric patients with more than 90% sensitivity for diagnosis of SA. Sub-periosteal or soft tissue collections of pus that may require surgical drainage can be better and earlier detected on the MRI images. In the setting of acute osteomyelitis, decreased signal on T1-weighted images and increased signal on T2-weighted images is a pertinent finding [3]. MRI with and without gadolinium contrast should be ordered to identify the presence of osteoarticular infection and assess the perfusion status of the joint [14].

Radionucleotide scanning is widely used to diagnose osteomyelitis early when plain radiographs appear normal. Technetium-99m (99mTc) scintigraphy is the most common used type of radionucleotide imaging. Browne et al. reported that bone scans fail to detect about half of the cases of methicillin-resistant *Staphylococcus aureus* (MRSA) osteomyelitis [9]. Indium 111–labeled leukocyte scans are another option for diagnosis of osteomyelitis [15]. At present, there is no evidence that supports superiority of radionucleotide scanning over MRI.

Molecular analyses of the synovial fluid using polymerase chain reaction (PCR) or next generation sequencing (NGS) may provide a useful adjunct to conventional culture for the identification of the infective organisms. These assays may be effective in the detection of atypical bacteria, such as mycobacterium, anaerobic pathogens and facilitate pathogen identification in culture-negative disease [7].

The use of serum or synovial molecular markers in the diagnosis of SA has been explored. Procalcitonin is an emerging biomarker for the diagnosis of SA with a high specificity for detecting joint infections, but studies have only been conducted in adults [16–19]. Another biomarker that has been explored in the setting of pediatric SA is LE. LE has been in clinical use for over 30 years, mostly as a point-of-care test for the diagnosis of urinary tract infection. The first application of this test in orthopaedic patient population was explored by Parvizi et al. [20]. In the latter study, investigators reported over 80% sensitivity and 100% specificity with the use of LE dipstick testing for diagnosis of periprosthetic joint infection (PJI). A recent study demonstrated that LE is a valuable test for diagnosis of native SA, but evidence for its efficacy in the pediatric age group is sparse [21].

Finally, the role of interleukin-6 (IL-6), a cytokine that is released by fibroblasts, has also been explored in the pediatric patient population. IL-6 is an acute-phase reactant that is thought to play a role in increasing CRP production by the liver [22]. IL-6 may be detected earlier than CRP in bone and joint infections, however, its associated cost and limited availability in the clinical setting have prevented it from becoming a mainstay in diagnosis of orthopaedic infections [22,23].

In conclusion, it appears that conventional serum tests, namely CRP and ESR, plain radiographs and synovial fluid analysis are the most important tests in work-up of a pediatric patient with suspected SA and/or osteomyelitis. Molecular biomarkers or techniques involving DNA sequencing may play a role in facilitating

diagnosis, as they have demonstrated superior sensitivity over conventional cultures.

QUESTION 2: Are there conditions where the erythrocyte sedimentation rate (ESR) and other blood tests are unreliable for diagnosis of pediatric musculoskeletal infections?

RECOMMENDATION: Yes. Serum tests including ESR, C-reactive protein (CRP) and absolute white blood cell (WBC) count might be unreliable for diagnosis of pediatric musculoskeletal infections in neonates, patients with rheumatological disease, post-trauma, post-surgery, patients with Lyme arthritis and those receiving intravenous immunoglobulin (IVIG) administration.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 88%, Disagree: 3%, Abstain: 9% (Super Majority, Strong Consensus)

RATIONALE

Various serology tests including WBC count, ESR and CRP are traditionally used to diagnose septic arthritis (SA)/osteomyelitis (OM) in children. Their diagnostic value is less than synovial fluid analysis and cultures that usually are utilized to prove the infection. ESR and CRP are almost always elevated in any inflammatory process (trauma, rheumatologic disease) with low specificity for infection [1,2].

Leukocytosis is not a typical feature in children with SA [3]. It has been shown that studies including more SA rather than OM have a lower rate of leukocytosis [4]. Results of an evidence-based study showed that overall diagnostic accuracy of peripheral WBC count for SA is not acceptable regardless of selected cutoff point [1].

The challenging age group in children is neonates and young infants in whom the infection is caused by organisms, such as coagulase-negative Staphylococci [4]. Owing to the non-characteristic features of osteoarticular infection, Sankaran et al. in a prospective study reported that fever, poor feeding and irritability are seen in less than 30% of infants with SA. Beside the paucity of sign and symptoms in this study, neutrophil count was found to be normal in 70% [5].

CRP is more sensitive than ESR for diagnosis of infection; its level rising as soon as six hours after disease initiation. Different studies have shown its usefulness in the diagnosis of SA [6,7], resolution of infection in neonates [8] and its ability to differentiate transient synovitis of the hip from SA [9]. Levine et al. reported that ESR and CRP are better as negative predictors for SA, particularly when the CRP level is less than 1mg/dL with an accuracy of less than 85% [8].

Lyme arthritis in children may be associated with clinical findings similar to SA. CRP and ESR levels are reported to be increased in 64% to 100% of patients with Lyme arthritis, respectively [10,11]. CRP and ESR were not found to be useful tests to differentiate Lyme disease and SA [12]. Administration of IVIG in children can also result in increased levels of ESR, interfering with diagnosis of SA/OM and rendering the test ineffective in monitoring response to treatment [13].

Even though CRP and WBC counts of synovial samples are believed to be useful tests for diagnosis of SA and distinguishing it from juvenile inflammatory arthritis (JIA), a recent report demonstrates that these tests might not be sufficiently specific as there is significant overlap in the value of these tests in both conditions [14].

In addition, the levels of CRP and ESR may be elevated following trauma and after surgical procedures [15], rendering these tests less useful in post-trauma and postoperative periods.

QUESTION 3: For pediatric patients with suspected septic arthritis (SA), does the clinical criteria override inconclusive laboratory tests?

RECOMMENDATION: For pediatric patients with suspected SA, the clinical criteria override inconclusive laboratory tests.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 91%, Disagree: 2%, Abstain: 7% (Super Majority, Strong Consensus)

RATIONALE

It is well known that there are no standard tests that can accurately diagnose SA in children [1–7]. Thus, it is not uncommon to face a situation where the diagnosis of SA is strongly suspected, but laboratory tests remain inconclusive [3,4]. Among all the existing diagnostic tests for septic arthritis, isolation of infective organisms from the synovial joint is considered as the gold standard for this condition [3,5,6]. However, the latter can hardly be considered a gold standard as the probability of isolating an infective microorganism from the synovial fluid of patients with SA ranges from 22%-82% [7]. Culture results are affected by numerous factors including antibiotic administration and the virulence of the infective organism.

To improve the yield of a culture, it is recommended that antibiotic treatment is initiated after joint aspiration has been performed. In case of negative culture, laboratory tests, clinical symptoms and radiological signs are important for the diagnosis of SA [1,7]. As no single diagnostic test for SA in children exists [8], it is recommended that the diagnosis of SA should rest on the opinion of experienced clinicians and override the laboratory tests [1,3,4]. A systematic review revealed that, despite the use of laboratory investigations, the gold standard for the diagnosis of SA is the level of clinical suspicion of a physician experienced in the management of pediatric patients with musculoskeletal infections [3,4,8].

Although analysis of the synovial fluid can be useful in the diagnosis of SA in children, aspiration of the joint may require administration of general anesthesia and is complicated. The decision to perform aspiration should rest with the clinician and be determined based on the degree of suspicion for SA. Diagnosis of SA should rely on less invasive tests as much as possible [5].

Despite the extensive literature investigating the clinical and laboratory features of septic arthritis, the number of studies that exist on the significance of clinical features and laboratory tests for diagnosis of SA in children is limited.

Among the eight published studies, one is a systematic review, two are retrospective studies, two are review articles, one is a community-based epidemiological study and two are case series [1–8]. Based on the evaluation of the available literature, we are unable to determine the most effective diagnostic protocol for SA in children. Among the reviewed studies, one proposes that not all children can be classified as having or not having SA on the basis of historical, clinical, laboratory or radiologic findings [8]. The latter raises the need for additional tests, such as joint aspiration.

Another study endorses the same principle recommending that any patient without clear-cut evidence for SA, or lack thereof, needs an examination of the joint fluid for diagnosis [1]. Another study reported that the diagnosis is rarely established by the history and physical examination, and the clinician is led to rely on ancillary tests, specifically the white blood cell (WBC) count from peripheral blood and other serological markers for inflammation, such as the erythrocyte sedimentation rate [4]. A retrospective study examined the incidence, etiology and clinical features of septic arthritis in children less than 24 months and concluded that the diagnosis of SA in children needed to be made based on a high index of suspicion and could not be excluded based on lack of fever and normal laboratory tests [2].

Based on our understanding of the literature, and in the absence of an absolute test, it appears that the diagnosis of SA in children needs to be made using a combination of clinical findings, laboratory tests and appropriate imaging. For patients with equivocal findings, clinical suspicion should override laboratory findings, because missing SA in a child, especially when caused by a virulent organism, can have serious consequences.

QUESTION 4: Is there a role for arthrocentesis (joint puncture) of an infected joint in a pediatric patient?

RECOMMENDATION: Yes. Arthrocentesis of an infected joint is effective for decompression of the joint. However, some children need arthrotomy.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 83%, Disagree: 11%, Abstain: 6% (Super Majority, Strong Consensus)

RATIONALE

Arthrocentesis (joint puncture) is one of the most valuable procedures for the diagnosis and treatment of joint diseases [1]. In children with septic arthritis (SA), arthrocentesis can be very useful for both diagnosis and as means of treatment [2,3]. It is safe and simple, but approaching the joint correctly, especially of the hip, is not possible for all physicians in emergency departments [4].

In a child with acutely swollen, red, painful joint and fever, if C-reactive protein (CRP) > 20mg/dL or erythrocyte sedimentation rate (ESR) > 20mm/h, then arthrocentesis may be indicated to confirm the diagnosis [5]. Arthrocentesis is also used as the treatment of SA in combination with antibiotic therapy. Ultrasound-guided aspiration of the hip evacuates pus, reduces damage to the articular surfaces, differentiates joint sepsis from other arthritides and helps direct antibiotic treatment [6,7]. Furthermore, there is a concern about the adverse effect of emergent open arthrotomy in severely inflamed joints, and it is debatable whether early decompressive arthrotomy is always useful [8–11].

In a retrospective study, hip arthrocentesis was found to avert the need for invasive surgery in more than 80 % of children (ranging from 3 months to 15 years of age) in a cohort of 261 culture-positive patients with SA. Outcome was comparable between arthrotomy and non-arthrotomy group. The study found that in the case of adjacent osteomyelitis, arthrotomy was more useful [12]. The results are supported by another study by Journeau et al. that reported favorable outcome in about 90% of the patients with hip arthrocentesis. They identified CRP > 100 mg/L, polymorphonuclear cell > 15,000, and ESR > 25 mm/hr as predictive of the need for arthrotomy [13].

In a prospective randomized trial, 201 consecutive children with the diagnosis of SA, arthrocentesis and arthrotomy were compared, and the patients were followed for one year. There were no differences regarding clinical outcome in any of the groups; hospital stay was lower in arthrocentesis group [8]. Smith et al. in a randomized control trial reported similar results for outcome of arthrotomy vs. arthrocentesis in 61 children with SA of the shoulder [10]. The findings of the latter study are also reflected in another study by Pääkkönen et al. involving nine children with SA affecting the shoulder [14].

Existing evidence for knee joint is different. Arthroscopic irrigation and decompression has been found to be successful in the majority of patients. The procedure can be performed through a single portal and without the need for a repeat procedure. In a retrospective study, around 40% of children older than three years who underwent a knee arthrocentesis required further arthrotomy to eradicate the infection and high initial CRP levels were identified as a predictor of aspiration failure [15].

Authors: Muhammad Amin Chinoy, Sher Wali Khan

QUESTION 5: Is there a role for percutaneous bone sampling (biopsy) for microbiological diagnosis of septic arthritis/osteomyelitis (OM)? If so, when should this be performed?

RECOMMENDATION: Yes. Percutaneous bone sampling (biopsy) is very safe and cost-effective and can be obtained from any site under the guidance of fluoroscopy or computed tomography (CT). It has a low sensitivity for microbiological diagnosis of OM that can be enhanced by the addition of histopathological examination. Literature suggests that bone sampling should be performed before initiating empirical antibiotic therapy.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 88%, Disagree: 7%, Abstain: 5% (Super Majority, Strong Consensus)

RATIONALE

OM is described as inflammation of the bone marrow and adjoining bone and is usually related with cortical and trabecular destruction. It can be caused by bacteria, fungi and a variety of other organisms [1]. Prompt identification and treatment of OM is necessary since undiagnosed cases can result in chronic pain, amputation and death. Even though clinical symptoms, inflammatory serological markers and imaging, such as magnetic resonance imaging (MRI), play an essential role in reaching a diagnosis of OM, the most important aspect of diagnosis relies on isolation of the infective organism from the infection site [2–4]. Pathogen identification and determination of its antibiotic susceptibility are paramount for successful treatment with antimicrobial therapy. Blood cultures may also be positive in a small number of patients with OM, which can guide antimicrobial therapy, so definite diagnosis and suitable therapy depend on tissue samples collected through bone biopsy [4].

Although surgical biopsy is also an option for confirming the diagnosis, percutaneous biopsy with fluoroscopic or computed tomography (CT) guidance has been proven to be a more reasonable, faster and more cost-effective modality with fewer complications [5,6]. The first percutaneous vertebral bone biopsy was performed by Ball in 1934. The use of image guidance was first seen with radiography in 1949, fluoroscopy in 1969, CT in 1981, MRI in 1986 and CT fluoroscopy in 1996 [6].

Literature review from the 1990's and early 2000's stated the accuracy of a percutaneous biopsy of vertebral lesions guided with CT or fluoroscopy ranged from 88% to 100% [6]. The recent and most comprehensive retrospective review done by Sehn and Gilula reported that 63 of 113 cases were positive when samples were tested histologically (55.7%) and only 28 of the 92 cases were positive when samples were investigated microbiologically (30.4%). Culture and/or pathology review was positive in 73 (64.6%) of the 113 cases. Pathology review along with culture of biopsy specimen supported a diagnosis of OM in 64.6% of investigated cases. However, the age of the participants ranged from 1 to 92 years [7]. This is in contrast to the study done in the 1990s and early 2000s [6].

Ballah et al. reported that there were 26 biopsies performed, 21 out of 26 biopsies were diagnostic (81%); 2/26 (8%) were false-negative extracting nonlesional tissue, 2/26 (8%) were nondiagnostic and 1/26 (4%) were technically unsuccessful. The diagnoses were as follows: 12/26 biopsies (46%) were OM; 3/26 (11%) biopsies were Langerhans cell histiocytosis; 3/26 biopsies (11%) were normal bone; 2/26 (8%) biopsies were malignant tumors and 1/26 (4%) biopsies were osteoblastoma. Of 12 children with OM only 3 had a positive culture; 9/12 (75%) children had a negative culture. They did not report any p-value or confidence interval. They concluded that percutaneous CT guided vertebral bone biopsy is safe in children with a high degree of diagnostic accuracy [8].

A systematic review and meta-analysis of 7 studies (later excluded 2 studies) indicated that image-guided percutaneous needle aspiration biopsy has a high specificity (99.9%) and, therefore, is quite effective when positive. However, it has low sensitivity (52.2%) and can miss a substantial proportion of patients. Image-guided spinal biopsy had a diagnostic odds ratio (DOR) of 45.50 (95% confidence interval [CI], 13.66–151.56), a likelihood ratio of positive test (LRP) of 16.76 (95% CI, 5.51–50.95), a likelihood ratio of negative test (LRN) of 0.39 (95% CI, 0.24–0.64), a sensitivity of 52.2% (95% CI, 45.8–58.5) and a specificity of 99.9% (95% CI, 94.5–100). The results of this study strengthen

the importance of image-guided percutaneous spinal biopsy [9].

Wu et al. observed that out of 41 (age range 3 to 82 years) histologically positive cases of OM, 14 (34%) cases were positive at culture. The proportion of positive culture results in confirmed cases of OM on the basis of histology was low. Patients who were on antimicrobial therapy in a 24 hour period of the biopsy, 24% had a positive culture, and the patients who were not on antibiotics had a 42% culture positivity rate. Larger prospective studies are required to investigate this finding further. They also advised or requested physicians to hold antibiotics for at least 24 hours before the biopsy [10].

Rankine et al. performed a retrospective study on 20 patients who had percutaneous spinal biopsies, with 8 out of 20 patients (40%) on antibiotics before the biopsy. An organism was isolated in 8 out of 20 cases (40%). Out of 8 patients on antibiotics, an organism was isolated in only 2 cases (25%). The result of the biopsy helped to modify the treatment in 7 of the 20 patients (35%). They also suggested that spinal biopsy should be done before starting antibiotic and a sample should be sent for both microbiology and histopathology [11].

Ng et al. reviewed the histopathological, cytological and microbiological results of patients who underwent bone and para-osseous biopsies between July 1977 and March 1996. The 502 biopsies were taken from 477 patients (age range for male patients was 5-86 years and for female patients was 2-86 years). Tumors were reported in 40% of the biopsies and infection in 16%. The latter study confirms the importance of bone biopsy in confirming diagnosis of infection and also detecting the presence of neoplasm, a differential diagnosis that needs to be born in mind when encountering pediatric patients suspected of infection. A bone biopsy can be taken from any site under the guidance of fluoroscopy or CT [12].

In conclusion, our extensive search of the literature has revealed one study evaluating the role of bone biopsy in children with the remainder of the studies being performed in an adult population. Based on the available evidence, we recommend that percutaneous bone biopsy under fluoroscopic or CT guidance is a reasonable, fast and cost-effective modality for diagnosis of OM and differentiating infection from neoplasm. It carries low complication rate but the ability of this test to isolate the infective organism in OM remains low. The above studies suggest that percutaneous bone biopsy shows high specificity but low sensitivity in microbiological diagnosis of OM but the combining results of microbiological examination with histological evaluation of the samples enhances the sensitivity. Literature also suggests that bone biopsy should be performed before initiating empirical antibiotic therapy in order to increase its yield for isolation of the infective organism.

QUESTION 6: Is there any role for polymerase chain reaction (PCR) or molecular testing in pediatric musculoskeletal infection (PMSI)?

RECOMMENDATION: PCR may be a useful diagnostic adjunct with the potential to expedite a preliminary diagnosis of PMSI in comparison to the use of microbiological culture alone. Furthermore, PCR can enable pathogen identification in cases where the organism is indolent, fastidious or difficult to culture. However, data remains sparse and further research is needed to standardize molecular techniques, minimize contamination and explore emerging molecular methods that are primer-independent.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 93%, Disagree: 2%, Abstain: 5% (Super Majority, Strong Consensus)

RATIONALE

The diagnosis of musculoskeletal infection is typically based on pertinent clinical findings, synovial fluid analysis and a positive gram stain or culture confirming the microbial identity of a pathogen [1]. Although culture results are used to identify the infecting organism and determine antimicrobial sensitivity, culture is often limited by sampling methodology, processing issues, early antibiotic administration, and/or the presence of hard to culture organisms [2–4]. PCR and other molecular techniques have been investigated to a limited

degree as diagnostic tools and are showing promise for improving PMSI diagnosis.

Evidence for the diagnostic use of PCR in PMSI is sparse. In a prospective study exploring the utility of PCR, Verdier et al. enrolled 171 pediatric patients with osteoarticular infection (OAI). From this cohort, 64 culture-positive specimens were identified, of which 9 cases were positive for *Kingella kingae*. When the 107 culture-negative specimens were tested with PCR, 15 additional cases of *Kingella kingae* were detected [5]. Similarly, Chometon et al. conducted a study of 131 patients with acute pediatric OAI in a single hospital and found that pathogen identification improved from 45% by culture alone to 66% with both culture and PCR testing [6].

Ferroni et al. performed a prospective study with 197 acute pediatric OAI cases in a single hospital and found that the use of PCR in addition to culture and histology increased bacterial diagnosis by 54%.

There is additional evidence for the utility of PCR aiding diagnosis of musculoskeletal infection from studies examining adult cases. However, the reported sensitivity of PCR varies widely in the literature from 43.8% to 92.5% and specificity ranges from 92.9% to 100% [7–9]. Despite this variation, investigators consistently conclude that the rapid availability of the results (<1 day) make PCR an adjunctive tool for guiding early treatment prior to the availability of culture results [7,8], especially in the setting of a negative culture [9]. It should be noted that these studies used different standards to compare to PCR performance; Bonilla et al. and Fenollar et al. used culture results as their gold standard, while Fihman et al. used clinician diagnostic judgment based on predetermined factors [7,9]. This significant inconsistency renders the results difficult to compare and interpret across studies.

PCR has also shown promise as a valuable tool for diagnosing tuberculosis affecting the bones and joints [10–12]. *Mycobacterium tuberculosis* is a particularly difficult organism to culture because false-negative results are relatively common. Therefore, a rapid, reliable diagnostic test is still needed. A study of 24 samples (21 patients) showed that PCR had 100% sensitivity and 87.5% specificity for identifying tuberculous disease affecting the bones and joints. However, two false-positive results were seen in patients who had previously been diagnosed with tuberculosis [10].

An infected joint can rapidly progress into a medical emergency. Rapid molecular diagnostic tools could play a crucial role in identifying and treating the infection promptly [13]. PCR is a sensitive, rapid and widely-available molecular methodology that can detect microbial pathogens in clinical samples. However, in order to obtain reliable and consistent results it is necessary to standardize PCR preparation protocols and take care to avoid contamination [1,13].

Further research is needed to investigate the role that PCR and other molecular methods can play in identifying a pathogen.

QUESTION 7: How can we differentiate between sickle cell crisis and septic arthritis/osteomyelitis (OM)?

RECOMMENDATION: A combination of clinical, laboratory and imaging studies are all needed for differentiating between sickle cell crisis and infection. A positive aspiration for infection from the joint or periosteum confirms the presence of infection while sequential ultrasounds in the absence of sub-periosteal fluid collection favor sickle cell crisis. Tri-phasic bone scan in the first 24 hours can differentiate vaso-occlusive crisis (VOC) from acute infection. Contrast-enhanced magnetic resonance imaging (MRI) is fairly accurate in differentiating infection from infarction.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 87%, Disagree: 0%, Abstain: 13% (Super Majority, Strong Consensus)

RATIONALE

Differentiating bone and joint infection from osteonecrosis (ON) in sickle cell disease (SCD) can be very challenging. Clinical presentation is an important tool in distinguishing OM from VOC in SCD: sudden, often severe pain; no or low-grade fever of less than 100 F (<38 c); inflam-

matory markers only mildly elevated; and elevated HB/HCT ratio are all indicative of crisis and ON [1–3]. Also, pain in more than one site is more likely to be a crisis and not OM [4,5].

Inusa et al. [6] in a retrospective study demonstrated that mean initial white blood cell count was 14.9 in VOC and 17.8 in OM. They reported mean C-reactive protein (CRP) as the more informative test in differentiating OM from VOC–86.4 vs. 39.8. Therefore, CRP should be included in the risk criteria for infection in an SCD patient with fever [7,8]. Radiographs in early phases of OM or VOC are usually normal, with periosteal reaction showing up in both conditions within the first 2 weeks [4,9].

Ultrasound scans alone can diagnose OM in SCD cases with 74% sensitivity and 63% specificity [10]. Ultrasound scan within the first six days shows periosteal elevation and/or fluid collection in 76% of OM, while 91% of VOC cases show no evidence of fluid collection. Repeat ultrasound is needed to confirm the diagnosis of VOC when fluid collection remains negative [6].

Combination of ultrasound and CRP was found to be a reliable, cost-effective measure in distinguishing OM from VOC [6]. Triphasic isotope bone scans and labeled WBC scans can be helpful in later stages [11–14]. Sequential radionuclide bone marrow scanning and bone scan within the first 24 hours differentiate bone infarction from acute infection [15,16].

T1-weighted MRI has low intensity in the medullary infarct and high intensity in T2-weighted images [4,11]. Contrast material enhancement on MRI may distinguish accurately between infection and infarction [17]. Un-enhanced bone marrow signal intensity on fat-saturated MRI images is not a reliable criterion for differentiation of infection from infarction according to Delgado [18].

Aspiration of pus from the subperiosteal region or joint, or positive blood culture remains the gold standard for diagnosing infection in SCD, bearing in mind that a negative blood culture does not rule out infection [8,19,20].

Treatment

Authors: Ali Parsa, Alexander J. Shope

QUESTION 1: What are the indications for surgical intervention in cases of osteomyelitis/septic arthritis? How should treatment progress and resolution be monitored?

RECOMMENDATION: Septic arthritis is an orthopaedic emergency and needs prompt surgical treatment. Based on current evidence, there are no clear indications for the timing of surgical intervention in cases of osteomyelitis. The current literature does suggest monitoring disease progression, treatment efficacy and resolution by trending C-reactive protein (CRP) levels.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 91%, Disagree: 3%, Abstain: 6% (Super Majority, Strong Consensus)

RATIONALE

The treatment of musculoskeletal infections in children has long been debated. Evidence has shown that it can be appropriate to treat this condition medically. However, surgery can play a critical therapeutic role for patients not responding to medical treatment or those presenting with massive bioburden in the joint that may require evacuation.

Osteomyelitis in the pediatric population often has overlapping clinical features with other diseases, making its diagnosis challenging [1]. Not only are the clinical presentations diverse, the epidemiologic aspects of the pathology also play a critical role in its therapy. Patient age, sex, socioeconomic status and even geographical location all point to different etiologies, making treatment choices challenging [1,2]. Patients living in the United States can be at particular risk of aggressive osteomyelitis infections due to the presence of highly virulent strains of methicillin-resistant *Staphylococcus aureus* (MRSA). Ninety percent of MRSA isolates found in the U.S. are related to the USA300 strain which is positive for *pvl* and *fnbB* genes–coding for the Panton-Valentine Leucocidin toxin and fibronectin binding factor respectively [3]. Patients contracting strains such as these are at increased risk of subperiosteal abscess formation, septic thrombophlebitis, endocarditis and large muscle abscesses [3]. Another pathogen, *Kingella kingae*, has also recently emerged as an etiology of osteomyelitis and septic arthritis with a milder clinical presentation as well as lower inflammatory markers and white-blood cell (WBC) counts [4]. This further emphasizes the diversity in which these conditions can present.

Because of the multifaceted nature of osteomyelitis, care of these patients requires a coordinated, multidisciplinary approach in order to avoid potentially devastating complications of a missed osteomyelitis diagnosis [1]. As with many conditions in medicine, early diagnosis and treatment initiation are paramount. Unfortunately, there are no gold standard tests to aid in the diagnosis of septic arthritis or osteomyelitis in the pediatric patient population [5]. Additionally, the lack of clear-cut surgical indications makes treatment plans complicated [1,6–9].

Osteomyelitis was found to be concomitant with septic arthritis in about 30% of cases [1,3]. Typically, bacteria seed in the metaphyseal region of long bones where capillaries make sharp turns resulting in serpentine routes of blood flow [1,3,5]. If the infection develops in the intracapsular portion of metaphyseal bone (i.e., proximal femur, humerus, radius or lateral distal tibia) there is a higher likelihood of extension into the joint space [1,3]. Joint space involvement creates an increase in intra-articular pressure, recruitment of leukocytes and subsequent release of cytokines, which can cause cartilage damage in as little as eight hours [4,10].

Proponents for surgical intervention have argued that the operative intervention can halt the disease progression [1,6,11]. Surgery and debridement of the joint can reduce the likelihood for osteonecrosis by enhancing the vascular supply to the bone, thereby allowing for improved antibiotic delivery and penetration to the site of infection [6]. Likewise, with osteoarticular involvement, decompressing and washing out the joint helps stem permanent damage by decreasing intra-articular pressure and reducing proteolytic enzymes resulting in degradation of the cartilage and sub-chondral bone [10,11].

Despite these valid arguments, studies have not been conducted that effectively define surgical indications for osteomyelitis and septic arthritis. Indications for surgery in the literature are based on expert opinions, case series and cohort studies with none providing evidence-based clinical guidelines for surgical intervention in the case of osteomyelitis [6,7,9]. Additionally, the surgical procedures used for osteomyelitis are diverse, ranging from bone biopsy and subperiosteal abscess drainage to more involved procedures, such as the creation of a cortical window and extensive debridement [1]. Dartnell et al. conducted a systematic review of the literature and found very little evidence to support surgical intervention in pediatric patients with osteomyelitis and/or septic arthritis due to a lack of randomized controlled trials [8]. At best, current recommendations for surgery include [1,6–8,12]:

- Failure to improve in 48-72 hours despite antibiotic treatment
- Presence of frank pus on aspiration of the joint
- Identification of sequestered abscess

However, none of these recommendations come with quantitative evidence from randomized controlled studies.

Septic arthritis is considered an orthopaedic emergency and necessitates prompt treatment [13–15]. Across the current literature, it is well agreed that septic arthritis requires surgical removal of the inciting materials [5,10]. Guidelines and appropriate randomized trials to establish statistical evidence are still lacking. Moreover, numerous suggestions of the exact joint decompression technique exist (i.e., arthrotomy versus arthroscopy versus needle aspiration).

El-Sayed et al. conducted a prospective controlled study to compare hip arthrotomy versus arthroscopy in the setting of septic

hip arthritis [13]. Open arthrotomy had been considered the gold standard at the time of his study. The latter study reported no statistical differences in clinical results (according to Bennett's clinical assessment criteria), such as prolonged post-operative joint aches, joint range of motion limitations or infection recurrence [13]. Mean hospital length of stay was shorter for the arthroscopic group compared to the arthrotomy group (mean of 3.8 days versus 6.4 days, $p < 0.0001$) [13]. The results of this study suggest that hip arthroscopy is a valid alternative to hip arthrotomy for septic arthritis of the hip joint. Similar findings were reported by another study [5].

For septic arthritis of the knee, arthroscopy tends to be the operative choice [12,13]. Again, data is lacking to support these claims. Other studies have suggested that arthrotomy may be better for septic arthritis of the shoulder and the hip joint due to the tight space in these joints to allow entry of arthroscopic instruments [10,12]. Baker et al. noted that arthroscopy can be a viable alternative as well in the shoulder and ankle joints [12]. Conversely, Peltola et al. report in their prospective randomized trial that most of the included patients in their study did not require any operative procedures beyond a diagnostic aspiration [16]. Despite the debate over the technique and necessity of surgical interventions, the literature does emphasize that early diagnosis and prompt treatment are paramount when caring for suspected septic arthritis patients [5,8,10,13].

Other studies have attempted to streamline the diagnostic approach to patients with suspected septic arthritis. Kocher et al. established a clinical algorithm in order to aid in early diagnosis of pediatric septic hips [14]. Their criteria included the inability or refusal of the patient to bear weight, history of fever (defined as an oral temperature >38.5 °C), a serum WBC count greater than 12,000 cells/mm^3 and an erythrocyte sedimentation rate (ESR) greater than 40 mm/hr [14]. Later studies found greater efficacy when incorporating CRP into this algorithm [17–19]. However, this clinical algorithm has not been fully validated across all populations and further studies must be carried out before it can be applied universally [15,20].

Despite significant heterogeneity in the literature regarding surgical indications and operative techniques for osteomyelitis and septic arthritis, there is more of a consensus on the use of CRP and ESR for aiding in diagnosis and monitoring treatment response [8,17]. CRP has been proven as an effective test for diagnosis and monitoring of response to treatment [5,8,10,16]. ESR was classically associated as a laboratory marker for osteomyelitis but has now been widely replaced by CRP [10]. The short half-life of CRP allows for more precise monitoring for efficacy of treatment. Decreasing CRP levels are indicative of treatment efficacy [8,16]. Pääkkönen et al. found that even with persistent pyrexia, decreasing CRP levels could be used to justify switching antibiotics from intravenous to oral [10]. They also report that they were able to safely discontinue antibiotics after 10 days as long as CRP levels were less than 20 mg/dL [10,16]. In circumstances when the CRP levels does not decline or continues to increase, further workup or additional interventions may be necessary as this suggests a suboptimal clinical response to the current treatment [16].

Author: Mahzad Javid

QUESTION 2: How radical should surgery be for osteomyelitis/septic arthritis?

RECOMMENDATION: In pediatric patients with osteomyelitis/septic arthritis who require surgical intervention, aggressive debridement and copious irrigation of the infected joint is required.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 89%, Disagree: 7%, Abstain: 4% (Super Majority, Strong Consensus)

RATIONALE

The treatment of choice for septic arthritis in children is irrigation and debridement of the septic joint to clear the joint of bacteria and destructive enzymes and also decrease the intra-articular pressure to avoid articular cartilage damage and ischemia [1,2].

Septic arthritis of the hip joint has been posited as an emergent condition in pediatric patients often requiring open arthrotomy as soon as confirmation of the disease is made with joint aspiration [1–5].

There are a few reports that show equivalent outcome for treatment of hip septic arthritis when arthroscopy versus arthrotomy was employed [6,7]. Repeated aspirations of the hip joint under ultrasound guidance was shown to be effective in 85% of children without the need for an arthrotomy [4,8–11]. The indication for surgical treatment of septic arthritis of other joints remains controversial. Drainage of any large effusion present in joints is usually advocated. In ankle, knee and shoulder joints, arthroscopic irrigation or aspiration and lavage may be appropriate [1,3].

There is no consensus for the time, type and extent of surgical procedures in patients with osteomyelitis [1]. Surgery is recommended in the presence of subperiosteal abscess, bone necrosis or direct invasion of the growth plate that may be seen in magnetic resonance imaging (MRI) images [2]. It is also indicated if a patient does not respond to antibiotic therapy, based on clinical examination, laboratory indices and imaging studies (particularly MRI) [1].

The decision to drain a subperiosteal collection seen on ultrasound cannot be based purely on the size of collection but needs to take into account the clinical findings of the patient and the response to antibiotic therapy [12–14].

During surgical intervention often a cortical window is created [1,15], but the optimal treatment for sub-periosteal abscess remains controversial in terms of whether or not a corticotomy or intramedullary drainage needs to be performed [1,16,17]. There is limited evidence to suggest that subperiosteal drainage alone is adequate management for a subperiosteal abscess [18–20].

Montgomery et al. [21] in a retrospective comparative study demonstrated that in patients with subperiosteal abscess, intramedullary drainage significantly decreased the need for repeat surgery. Another factor to consider when dealing with pediatric patients with septic arthritis is the virulence of the infective organism. In patients with methicillin-resistant *Staphylococcus aureus* (MRSA) infections, more aggressive surgical intervention is warranted, as these patients are at risk of relapse and often need repeated surgeries [15,22–24].

QUESTION 3: Is there a role for arthroscopic washout in children with septic arthritis?

RECOMMENDATION: Yes. Arthroscopy is a useful tool in the treatment of septic arthritis in children.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 83%, Disagree: 10%, Abstain: 7% (Super Majority, Strong Consensus)

RATIONALE

Early diagnosis of septic arthritis (SA) in the pediatric age group is essential in order to avoid adverse sequelae associated with delayed SA, such as osteonecrosis, chondrolysis, relapse or recurrent SA and sepsis, and is more important than the type of drainage[1–3].

For decades, the prevailing treatment of pediatric SA after early diagnosis was open arthrotomy, irrigation and debridement [2,4,5]. The optimal technique for drainage is controversial between needle aspiration, arthrotomy or arthroscopy. Arthroscopic drainage in adults with knee SA is the accepted treatment of choice, as functional outcome and success of treatment is better using this method of treatment [6,7]. Arthroscopic treatment of SA in pediatric patients is defined as a successful option for septic arthritis of the hip, knee, ankle and shoulder in children [8,9].

Despite concern about traction in septic hips during the infection process, several studies have demonstrated its safety [10–13].

Kim et al. and Chung et al. reported good results of hip arthroscopy utilization in SA [11,14,15]. In a prospective comparative study on hip SA, children treated arthroscopically had better functional outcomes (90% excellent vs. 70% in open arthrotomy group), significantly shorter hospital stays and a lower rate of scarring due to the less invasive nature [16].

A recent study with a 2.5-year follow-up supported these results [9]. In these reports, all repeated drainage was done arthroscopically, and it was safe for even very young children.

In a 7-year follow-up comparative study of arthroscopic washout vs. open arthrotomy, Johns et al. reported reduced rates of repeat drainage, earlier knee range of motion and weight-bearing in the arthroscopic arm; however, these trends did not reach a statistically significant difference [17].

In a series of 76 children with arthroscopically-treated septic arthritis, a combination of arthroscopic lavage and antibiotic therapy successfully eradicated infection in 91% patients, and open revision was only required in 4% of these cases [18].

In summary, arthroscopic washout is a useful procedure for the treatment of pediatric septic arthritis, but the evidence is weaker than in the adult literature. Limited sample size and an absence of randomized clinical trials are evident in both knee and hip SA in the pediatric setting. Thus, there is no definitive evidence to support arthroscopic washout over open arthrotomy in children.

QUESTION 4: Should the length of antibiotic usage be different for a primary septic arthritis (SA) versus osteomyelitis (OM)?

RECOMMENDATION: Although there is a tendency towards prescribing a longer course of antibiotics in pediatric patients with OM compared to primary SA, this practice is not based on conclusive evidence.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 93%, Disagree: 2%, Abstain: 5% (Super Majority, Strong Consensus)

RATIONALE

For decades, it has been believed that a prolonged course of antibiotic therapy (four to six weeks) is necessary to improve long-term outcomes when treating OM and SA in children [1–3]. In recent years, the efficacy of prescribing a prolonged course of antibiotics in the treatment of SA has begun to be questioned. Recent studies, including clinical trials, have demonstrated that a shorter duration (less than one week) of antibiotic therapy, in particular intravenous antibiotics, is effective in treating selective groups of pediatric patients with musculoskeletal infection while reducing length of stay, complications and healthcare costs [4–9].

Jagodzinski et al. demonstrated in a prospective study that three to five days of parenteral antibiotic therapy was sufficient for treating osteoarticular infection in children [10]. However, the Infectious Diseases Society of America (IDSA) currently recommends

a six-week course of antibiotics are administered to children with methicillin-resistant *Staphylococcus aureus* (MRSA) infection of the musculoskeletal system [11].

There is also no consensus or published studies about the optimal transition time from intravenous to oral antibiotic therapy in pediatric osteoarticular infection. There is, however, agreement in clinical practice that a transition from parenteral to oral antibiotics should occur when clinical signs and serum laboratory markers improve [12–14].

An extensive search of the literature revealed 33 retrospective observational studies related to management of pediatric musculoskeletal infections. The median length of antibiotic usage in these studies ranged from two to five weeks for SA patients and three to eight weeks for OM patients. Many of these studies had small sample sizes, short follow-up duration and heterogeneous patient populations, thus precluding meaningful comparison. In studies analyzing both SA and OM populations, a longer duration of antibiotics was consistently reported for OM patients [15–17].

There have been no high-level studies examining the appropriate length of antibiotic treatment for pediatric patients with SA vs. OM. In the absence of such concrete evidence, it remains unclear if the length of antibiotic treatment should be different for primary SA vs. OM. From the results of review of the available literature, it appears that uncomplicated cases of SA may be treated with a shorter duration of antibiotics than OM. This aligns with current guidelines from the European Society for Pediatric Infectious Diseases as well as the Australasian Society for Infectious Diseases, which both recommend an average of two to three weeks of antibiotics in SA and three to four weeks of antibiotics in OM [18,19]. Australian Therapeutic Guidelines suggest similar durations of three weeks in SA and three weeks minimum in OM [20,21]. However, length of antibiotic usage should be evaluated individually and guided by clinical response. There is a paucity of data on antibiotic duration in neonates, immunocompromised patients, patients with bone abscesses, those with chronic OM and infections caused by MRSA. The optimal length of therapy in these groups is yet to be defined. Thus, larger prospective randomized clinical trials of methodological rigor are required.

QUESTION 5: Do steroids have a chondroprotective effect in children with septic arthritis (SA)?

RECOMMENDATION: Based on available pre-clinical and clinical studies it appears that the concurrent use of corticosteroids and antibiotics may have a protective role in the management of SA in the pediatric patient population.

LEVEL OF EVIDENCE: Limited

DELEGATE VOTE: Agree: 58%, Disagree: 20%, Abstain: 22% (Simple Majority, NO Consensus)

RATIONALE

SA can lead to severe joint disabilities in about 30% of affected children. These disabilities include restriction of bone growth, chondral destruction, stiffness, pathologic fracture, limb-length discrepancy, subluxation and chronic dislocation of the joint [1,2].

The processes leading to these sequelae are thought to be due more to inflammatory responses than direct damage caused by

microorganisms. Rapid proliferation of bacteria within the joint space activates a cascade of pro-inflammatory cytokines including, interleukin (IL)-1 beta, IL-6, IL-17 and tumor necrosis factor (TNF)-α [3]. These cytokines, in conjunction with the TNF receptor-ligand family receptor activator of nuclear factor kappa-B ligand (RANKL), are believed to play a critical role in the activation and proliferation of osteoclasts, leading to bone resorption. Specifically, the interaction between RANKL and its receptor, RANK, has been shown to be required for osteoclast differentiation. Expression dysregulation of these factors in SA can lead to significant osteolysis [4,5]. In addition, increased synovial fluid and joint effusion in SA can obstruct blood supply of the joint, leading to chondrocyte necrosis, even during the early hours of infection [6].

Glucocorticoids have an established role in suppressing the release of proinflammatory cytokines in almost all acute or chronic diseases [7]. They are used to control inflammatory conditions affecting the joint, such as rheumatoid arthritis and ankylosing spondylitis. Corticosteroids also reduce the production of proteolytic enzymes, such as elastase, collagenase and synovial matrix metallopeptidase-1 (MMP-1), thereby preventing the chondral degradation process [7,8]. Despite the use of corticosteroids in inflammatory conditions, they are avoided in patients who have infections due to their immunosuppressive effect and their potential to exacerbate infection. However, recent evidence suggests that the concurrent use of corticosteroids with antibiotics improved the care of patients with central nervous system infections, pneumonia, upper urinary tract infection and sepsis [9–12].

The chondroprotective effect of glucocorticoids was investigated by two separate studies in 1996. Stricker et al. and Sakiniene et al. investigated the chondroprotective effect of corticosteroids on the course of SA [13,14]. Both studies utilized animal models to investigate if the administration of glucocorticoids had any influence on the levels of circulating inflammatory mediators. Stricker et al. employed the rabbit model and Sakiniene et al. utilized a mouse model to demonstrate that the administration of glucocorticoids resulted in improvement in symptoms in the animals and a significant decrease in serum levels of inflammatory cytokines at two weeks.

Extensive search of the literature revealed four clinical studies that relate to this subject (Table 1). These studies consist of two double-blinded randomized control trials, one non-randomized clinical trial and one retrospective study [15–18]. The findings of the studies are summarized in Table 1. All studies demonstrate improvements in clinical symptoms, length of hospital stay, reduced use of antibiotics or faster return to normal of serum inflammatory markers, such as C-reactive protein (CRP). In 2015 a meta-analysis was published regarding the use of corticosteroids in SA that included three of the aforementioned studies [19]. The finding of the meta-analysis was that the use of corticosteroids combined with antibiotics resulted in an improvement in the outcome of management of SA in children.

Despite the availability of evidence to support the use of corticosteroids in pediatric patients with SA, some concerns still remain. These concerns are:

1. The studies do not specifically seek adverse effects associated with the administration of corticosteroids.
2. Long term follow-up on patients receiving steroids is not available.
3. Total participant number of these studies is low.
4. Optimum dose, duration and route of prescription of corticosteroids is not clear yet.

TABLE 1. Summary of studies

Author (Year)	Study Design	Participants	Treatment Protocol	Results (Follow-up)
Odio et al. (2003) [15]	Randomised clinical trial	100 children	4 days of dexamethasone + AB	Significant decrease of joint dysfunction (12m) Quicker normalization of CRP Earlier symptoms relief Decreased IV antibiotics days
Harel et al. (2011) [16]	Randomised clinical trial	49 children	4 days of dexamethasone + AB	Significant decrease of joint dysfunction (12m) Became afebrile earlier Quicker normalization of CRP Decreased IV antibiotics days Decreased hospitalization
Arti et al. (2014) [17]	Non-randomized clinical trial	60 children	4 days of dexamethasone + AB	Decreased hospitalization Better final ROM Decreased local sign of inflammation Higher ESR reduction rate
Fogel et al. (2015) [18]	Retrospective	116 children	Few days of dexamethasone + AB	Rapid clinical improvement Quicker normalization of CRP Decreased IV antibiotics days Decreased hospitalization

The aforementioned concerns are important enough to justify the need for larger scale prospective studies with a longer follow-up that examine the benefits as well as the potential adverse effects of corticosteroids administered to pediatric patients with SA.

QUESTION 6: What is the optimal management of septic arthritis/osteomyelitis (SA/OM) caused by methicillin-resistant *Staphylococcus aureus* (MRSA)?

RECOMMENDATION: Patients with MRSA infection should be started on an antibiotic regimen, such as vancomycin, intravenously followed by linezolid, which is effective against this organism. Early consideration for surgical treatment and close monitoring is essential in pediatric patients with musculoskeletal MRSA infection to reduce the high prevalence of complications and late sequelae that are often seen.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 85%, Disagree: 11%, Abstain: 4% (Super Majority, Strong Consensus)

RATIONALE:

In past decade, the prevalence of MRSA in SA and acute OM has dramatically risen between 3- to 10-fold [1–3]. Compared to methicillin-susceptible *Staphylococcus aureus* (MSSA) infections, patients with MRSA have more extensive areas of soft tissue destruction, more rapid spread of infection and experience higher mortality rates [2–4]. The course of treatment of these patients is also protracted with a longer length of hospital stay, need for surgical intervention and an increased risk of complications, such as persistent bacteremia, deep vein thrombosis, pulmonary embolus, pathologic fractures and other long-term sequelae [1,2,5–10].

The severity of MRSA infections may be related to virulence factors, such as Panton-Valentine Leukocidin (PVL) found in many MRSA strains [11,12]. MRSA strains may also contain specific virulence factors that are linked to increased soft tissue destruction, such as α-hemolysin and α-type phenol-soluble modulin [3].

Pediatric patients with MRSA infections are more systematically unwell with higher temperatures and increased tachycardia. In addition, they present with even higher leukocytosis (or absolute neutrophil count), greater elevations in erythrocyte sedimentation rate and C-reactive protein but lower hematocrit values [5,7,10,13].

Commencing appropriate empiric antibiotics in these patients is paramount to improve outcomes. Children with suspected MRSA SA or OM should be started on intravenous vancomycin or clindamycin. Daptomycin or Linezolid are alternatives for the treatment of MRSA infections in children. The duration of therapy should be individualized based on the response to treatment. A minimum course of three to four weeks for SA and four to six weeks of antibiotics for OM is recommended [4,14].

Cultures should ideally be obtained before initiating antibiotics in patients with musculoskeletal infection, especially if MRSA is suspected. Aspiration of the affected joint and obtaining blood cultures helps isolate the infective organism and should be part of the initial work up of these patients [14,15]. New diagnostic methods, such as real time polymerase chain reaction (PCR), may be useful in the rapid identification of MRSA or other infective organisms [5].

Appropriate imaging, such as magnetic resonance imaging (MRI), should also be part of the work up since this allows for localization of the infection and determination of the extent of disease. MRI may also help with surgical planning to ensure a more thorough debridement and decompression of infected areas [10,15,16].

Images may also reveal subperiosteal abscess formation or the presence of SA in the hip. The presence of such findings lead to the need for early surgical intervention since antibiotics cannot typically penetrate large abscess cavities. Compared to MSSA infections, MRSA infections are more invasive and have a higher rates of abscess formation. Thus, they require surgical intervention more frequently and a higher number of repeat procedures [5].

Aggressive surgical management during the initial procedure, involving opening a surgical window and intramedullary irrigation, is necessary to prevent the need for subsequent reoperation. Close monitoring of patients is critical to prevent complications and reduces long-term sequelae. Patients who fail to respond to antibiotics should undergo prompt surgical interventions. Repeat imaging should also be considered in patients who are not responding to treatment in order to determine persistent infection and assess the extent of bony and soft tissue involvement [6,10,11,14,16].

In summary, MRSA infections of the musculoskeletal system in children may have serious complications. They require early administration of antibiotics and may necessitate multiple surgical interventions. These patients often have a protracted hospital course and require vigilant monitoring to minimize the risk of complications.

QUESTION 7: What is the best management for mycobacterium tuberculosis (TB) of the musculoskeletal system in children?

RECOMMENDATION: Mycobacterium TB periprosthetic joint infection (PJI) must be treated in collaboration with an infectious disease specialist, noting that the duration of treatment (minimum six months and up to two years) and the type of antimicrobials (usually a combination of four drugs) is determined based on the resistance profile of the pathogen.

LEVEL OF EVIDENCE: Moderate

DELEGATE VOTE: Agree: 86%, Disagree: 2%, Abstain: 12% (Super Majority, Strong Consensus)

RATIONALE

There is an agreement that anti-TB medications can eradicate most of the bacilli and prevent both relapse and drug resistance. The current recommendation for treatment length of extra-pulmonary TB in children is six months. However, these recommendations do not apply to osteoarticular infections and meningitis. Almost all available guidelines strongly recommend 12 months of anti-TB treatment for osteoarticular TB [1–5].

The recommended regimen for children with suspected or confirmed osteoarticular TB is a four-drug regimen consisting of Isoniazid (INH), Rifampin (RIF), Pyrazinamide (PZA) and Ethambutol (EMB) for 2 months, followed by a two-drug regimen of Isoniazid and Rifampin (HR) for 10 months [6].

There is limited literature that describes how to treat children with drug-resistant TB. For mono-drug resistance to either Isoniazid or Rifampicin, the recommendation is for 6-9 months of a three-drug regimen consisting of the other susceptible antibiotics from

TABLE 1. Recommendations for treatment of resistant TB in pediatrics

	Initial Phase	Maintenance Phase
INH-monoresistance TB	RIF + PZA + EMB (2 months)	RIF + PZA + EMB (4-7 months)
RIF-monoresistance TB	INH+ PZA + EMB + FQN (2 months)	INH + EMB + FQN (10-16 months)

INH, Isoniazid; EMB, Ethambutol; RIF, Rifampicin; PZA, Pyrazinamide; FQN, Fluoroquinolones; TB, Tuberculosis

the conventional four-drug regimen (Table 1) [3,7,8]. For multi-drug resistant (MDR) TB, all guidelines recommend a longer treatment period of up to 24 months with all four anti-TB drugs [3,7,9]. Evaluation of the organism's drug susceptibility profile should also be conducted [3,7,9].

While some authors have reported favorable results with chemotherapy and non-operative splinting of the affected joint(s), others have recommended debridement of focal bony involvement and arthroscopic or open synovectomy to decrease the overall bioburden of infected material [10,11].

Arthrodesis, especially of the hip joint, may be an option in the event of severe destruction of the joint secondary to infection [12]. Orthopaedic interventions in spinal TB may occasionally be recommended to prevent deformity of the spine in pediatric patients. These procedures may include surgical intervention, application of a brace or cast in addition to standard chemotherapy. Proper immobilization of the growing spine in pediatric patients may help achieve a solid fusion without surgical procedures.

Surgical intervention is reserved for patients with formation of a large anterior column abscess, severe kyphotic deformity or progressive spinal deformity despite chemotherapy [13,14].

QUESTION 8: What is the role of host gene expression and severity of acute osteoarticular infection in children, especially methicillin-resistant *Staphylococcus aureus* (*S. aureus*), or MRSA, infection?

RECOMMENDATION: Unknown. The limited literature available suggests altered host gene transcription related to the balance of the body's adaptive and innate immune responses may increase pediatric patients' susceptibility to severe osteoarticular infection, particularly in cases of MRSA. However, much more investigation is needed to determine which genes are most useful and how they can be utilized to help physicians anticipate the course of infection in a given patient.

LEVEL OF EVIDENCE: Consensus

DELEGATE VOTE: Agree: 75%, Disagree: 3%, Abstain: 22% (Super Majority, Strong Consensus)

RATIONALE

The severity of osteoarticular infection in otherwise healthy children varies greatly, even in the setting of infection by the same pathogen. Some pediatric patients experience a mild course that allows them to be discharged after a few days of hospital admission with antibiotic therapy. Other patients experience a protracted course and require major surgical intervention as well as intensive care management [1–3]. The contribution of genetic mechanisms to this wide range of clinical manifestations has been investigated to a limited extent. A similar diversity in illness severity has been observed in neoplastic and rheumatologic disorders, where there is evidence that ribonucleic acid expression plays a role in the presentation of these conditions [4–6]. Chaussabel et al. used gene expression microarrays in patients with seven autoimmune-related conditions and identified transcriptional changes ("diagnostic signatures") that could be used to distinguish between these respective conditions [7]. Identifying a parallel set of transcriptional diagnostic indicators for the severity of osteoarticular infection may enhance the ability of physicians to treat this condition.

S. aureus is one of the leading pathogens causing hospital-acquired infection and MRSA infection is associated with over 6,000 deaths/year in the United States [8]. In a series of 99 children hospitalized with *S. aureus* infection, investigators used microarray analysis to characterize the transcriptional profiles in whole blood. Significant heterogeneity was observed in host signatures and transcriptional changes were identified. Furthermore, this heterogeneity was found to be associated with a more severe course of disease. Overall, patients with invasive *S. aureus* infection had an exaggerated expression of genes associated with the innate immune response and a diminished expression of adaptive immunity [9].

Ardura et al. conducted a study comparing gene expression in peripheral blood monocyte cells (PBMC) between 53 children with invasive *S. aureus* infection and 24 healthy children. Analysis of PBMC gene expression showed that patients with invasive *S. aureus* had lower numbers of central memory CD4+ and CD8+ T-cells and increased numbers of CD14+ monocytes versus healthy controls [10]. Ramilo et al. compared the immune system response in patients with *Escherichia coli* infection versus those with *S. aureus* infection. Their findings support the specific pattern described by Ardura et al. They found that patients with *S. aureus* infection had altered host gene expression associated with their adaptive immune response [11]. Gaviria-Agudelo et al. reported on a cohort of 12 pediatric patients with acute hematogenous osteomyelitis caused by MRSA, and they identified specific genes which correlated with the severity of disease in the early hospitalization period. Among the five distinct genes that were identified, three were up-regulated (P2RX1, SORT1, RETN) and two were down-regulated (LOC641788, STAT 4). STAT4 down-regulation showed the strongest correlation with disease severity [12].

While these findings provide some initial evidence for the role of host gene expression in the severity of acute osteoarticular infection in children, the literature on this topic remains sparse. Further studies are needed to examine this connection, particularly studies with larger sample sizes. An enhanced understanding of host gene expression patterns and the transcriptome in osteoarticular infection could enable physicians to better anticipate the risk of developing chronic osteomyelitis and, ultimately, facilitate personalized patient management strategies.
